FALL, 1976

To Andy, with love.

ABSTRACT

The undue emphasis by linguists and A.I. Researchers on language structure and generation, at the expense of methods of acquisition, prompted Ian McMaster, in 1975, to propose a Comprehensive Language Acquisition Program (CLAP), emphasizing comprehension. This program differs from its predecessors in its completeness and its realistic combination of modelling and pragmatism. In support of CLAP's feasibility, a Vocabulary Acquisition System was programmed, showing promise for learning input words in relation to their corresponding referents in a static environment.

A Verbal Acquisition Module is now proposed as an extension of VAS to include events in its environment, with representations patterned after Schank's conceptualizations. The module is seen as another step towards the fulfillment of the larger language acquisition system, as it was proposed, or with modification.

After a brief introductory chapter, previous related research in psycho-linguistics and computer science is presented. CLAP is discussed as a first step towards the specification of a complete acquisition model, containing all the required ingredients though lacking sufficient detail for programming at this time.

Extending processes similar to those employed by VAS,

VAM correlates words with concepts relating to actions and events, whose representation is inspired by Schank's proposed structures for actions and events.

Some possible extensions of this work and further research prospects are mentioned in the final chapter.

INTRODUCTION

Artificial Intelligence (A.I.) is the field within
computer science concerned with the mechanical performance
of tasks previously assumed to require human intelligence.

> Problem-solving, perceptual, and linguistic
> competence all seem to depend upon prior knowledge
> of the task domain being present a priori in the
> computer. Hence the question of how a computer
> can acquire, represent, and make use of the
> knowledge of the world, is the main problem of AI.
> <Raphael, 1973, p. 9>

Computers have been programmed to answer questions, play
games, and solve problems when provided with the necessary
information and means of using it. Some such models of
intelligent activity have been more elegant than others, the
more impressive ones appearing to understand and think
rather than to trivially manipulate the input to produce the
output.

Modelling, in the strict sense of the word, would
require a precise definition of the process to be modelled.
Human cognition, still far from being completely understood,

cannot be adequately modelled. The notion of "model" must require only the simulation of performance, not processes. The current state of psychological expertise need not discourage work in artificial intelligence. Although intelligence in any non-human species is measured by human standards, imitation of such behavior by machine, in any manner which is sophisticated enough to be termed intelligent, can be not only a useful tool for experimenting with machine intelligence, but may well provide clues to how people think.

The ability to communicate through language is traditionally thought to be one of the distinguishing traits of man. Computers have been used to test linguistic transformational theories and to implement would-be mechanical translators. In the area of A.I., Winograd <1971,1972> has developed SHRDLU, a robotic system which demonstrates a remarkable ability to relate verbal input to its knowledge of the universe, represented by a world of various geometric BLOCKS which it can manipulate and "see". The presence of an environment gives substance to meaning. Only when language expresses meaning does it interest the A.I. Researcher; and only in the context of an environment can there be subject material for meaningful expression.

Winograd's system begins with a pre-defined language. Except for a limited number of recent studies <see Chapter

3>, little A.I. research has been devoted to the behavioral
processes involved in acquiring the use of language as a
tool for communication. The process of language learning,
of how and why a child can learn to understand and speak, is
one of the most fascinating of all aspects of language use.
A complete model of language performance will necessarily
include a theory of the process of language learning, as has
been emphasized by Schwarcz <1967>.

1.1 A Comprehensive Language Acquisition Program

A Comprehensive Language Acquisition Program (CLAP) has
been proposed by Ian McMaster <1975> as a system for
acquiring natural language, given a subset of descriptive
sentences input from a terminal, an internal representation
of an environment, and a means of receiving inputs
consisting of actions on the environment (a), approval or
disapproval (r), an utterance (u), a stimulus to output (s),
or a variety of combinations of these <McMaster, 1975,
pp. 89-90>. Eventually, the system learns to converse.

The acquisition system is based on five sequential
learning strategies. The emphasis is on learning to
understand, production being dependent on comprehension.
The first strategy involves learning to segment lexical
strings and to associate meaning with these segments. Once

CLAP has reached the point where it understands more than
one word of a given sentence, it can attach some import to
word order (strategy 2). Structural Generalization,
Conflict Resolution, and the Use of Discourse complete the
five strategies, which will be described in Chapter 3.

1.2 The Next Step

CLAP is a proposal for a program which would acquire
language. To demonstrate the feasibility of programming
such a model, McMaster <1975> wrote VAS (Vocabulary
Acquisition System). VAS associated a word and its
corresponding concept (which was an entity, attribute, or
relation) through weighted association links. However, VAS
could not manipulate objects, nor could the user. If object
movement is allowed within a scene, perhaps a system
patterned after VAS could also acquire action-concept
associations.

A major problem in our design of a verbal acquisition
module (VAM, to conform with the trend to give pet names to
such projects) is the internal representation of an action
on the environment, and the event surrounding its
occurrence. Roger Schank <1973b> suggests that all
conceptualizations, or sentences, can be reduced to a
structure built around primitive actions. This claim will

be explored further in Chapters 2 and 4.

We shall assume that such actions as the child can
recognize nonlinguistically provide a conceptual structure
onto which a lexicon can be mapped. Those environmental
modifications which were too subtle for the child to notice
will be ignored until he has enough experience to understand
the concept. Before this, however, the structure exists,
according to Schank, in which slots will later be filled.[1]

Changes in the environment, as well as concepts of
objects and their attributes, will all be part of VAM's
focus of attention, which contains those portions of the
environment noticed by VAM at a particular time. This
list of data base elements will be built by the programs
required to carry out a particular event. Some programs
will correspond to the conceptualization level of Schank's
schema. Others will represent the primitive actions chosen
for VAM's environment. Objects involved will fill slots in
the list, while the relationships will be derived from the
relational position of objects to each other. VAM will link
the input lexemes of the utterance to these concepts.

―――――――――――――――――

[1] "...the conceptual apparatus that underlies adult language
is present in a child before he has finished his first year
of life. It is this conceptual apparatus that guides
language learning and in fact facilitates the infant's
handling of the world in general." <Schank, 1973c, p. 1>.

Although an attempt will be made to make this system
psychologically and linguistically plausible, it should not
be construed to be an exact model of human cognitive
processes, for reasons stated above.

1.3 Overview

Psychology, linguistics, and, to some extent, computer
science have made contributions in the area of child
language acquisition. Chapter 2 is concerned with relevant
discoveries in these disciplines. After looking at a few of
the more interesting language acquisition models, Chapter 3
will examine CLAP's components and strategies. In Chapter
4, the Verbal Acquisition Module will be described as a
continued partial implementation of the first of CLAP's
strategies. According to CLAP's proposed scheme of
implementation <McMaster, 1975>, the number of times a word
has been used in connection with a concept, in conjunction
with the number of times the word and concept have been used
independently, will be considered in determining whether and
to what extent a word should have a concept as its meaning.

The major contribution of this work will be the
critique of prior work and its generalization to the
acquisition of verbs. Input will include utterance-action

pairs, which were absent from the input to VAS. Finally,
the results of programming this component will be discussed,
with consideration of problems, suggestions for improvement,
and directions for further research.

2

PSYCHOLINGUISTICS

The linguist's approach to acquisition has been predominantly concerned with the acquisition of syntax, as evidenced in production samples. Little material is available on holophrasis, the one-word utterance. It is usually discarded as uninterestingly trivial in structure. Yet the child's first word probably holds all the intended meaning of an adult sentence <Brown, 1973>.

Language acquisition research tends to ignore the presence of meaning; at best, its existence is acknowledged in a passing comment, to the effect that there is not enough known about the role of meaning in language learning. As systematic as language may appear, it has no significance without its associated meaning. Although syntax is important, it is a late component in a long process which begins at (or possibly even preceding) birth <Schank, 1973a>.

It is our belief that meaning is not only a valuable
tool, but a necessary component in the acquisition process.
Instead of being preoccupied with the acquisition of
language structure, we agree with Macnamara <1972> that the
first meanings are acquired independent of language, and
that the first words are then related to the meanings of the
utterance through the situational context. A parent's
intentional meaning - through expression, tone of voice, and
gesture - can often be understood before the associated
utterance. The meanings can refer to the physical
environment (the only reference in our model), the feelings
of the child, his ideas or concepts, and his attitudes
regarding truths <Macnamara, 1972>.

Furthermore, understanding of language precedes
production. One need only observe a non-speaking infant to
realize that he can understand scoldings and carry out
commands. As pointed out by Reeker <1974>, what is
important is the child's mental grammar, which is the only
true test of competence. Unfortunately, the inaccessability
of this grammar through performance data, coupled with its
rapid advancement and the variations between the grammars of
children at a given age, require the linguist to rely on the
data he has. The first words spoken provide one of the
easiest clues for determining which words are associated
with correct meanings, with a minimal amount of

interpretational bias. Linguists also use this data to
infer a grammar of the child's language as it stands.

The experimenter can only infer linguistic competence
from production performance. There are problems with this
approach. It is too easy to become subjective, imposing an
adult interpretation of the child's language. It is also
difficult to elicit required data to prove or disprove any
hypotheses about language acquisition. If a word or concept
is not produced, is it because it is not yet mastered,
because it was not detected at the right time, or because
there was simply lack of a need to use it? Yet we can make
some conjectures of what a child has internalized by
observing his actions and listening to his speech.

2.1 The Genesis of Acquisition

Among questions pertinent to verbal acquisition which
have been raised by both linguists and psycholinguists are
three whose answers are still disputable: (1) what is the
nature of what we will henceforth loosely refer to as the
language acquisition device (LAD)? which the child brings
to the language-learning situation; (2) what is the

_____

1 This is not to be equated with the innate mechanism
described by Chomsky <1965>.

influence of the linguistic environment on the child's
learning of a language; and (3) what strategies precede the
first spoken sentences? These will each be explored in the
following sections.

2.1.1 LAD

Not much of a concrete nature can be said about the
language acquisition device.[2] There are two points of view
concerning the type of entity the LAD might be. On the
basis of putative language universals, some suggest that the
child has a built-in sense of the hierarchy of grammatical
categories and knowledge of the basic grammatical relations.
On the other hand, others prefer to regard only the
procedures and inference rules as universal <Bowerman,
1973>. Anderson and Bower <1973> suggest looking to
evolution as a clue:

> Both in the evolution of man and in the
> development of the child, the ability to represent
> perceptual data in memory emerges long before the
> ability to represent linguistic information. We
> believe that language attaches itself to this
> underlying conceptual system designed for

----

[2] "...the question of the innate apparatus which the child
brings to the language-learning situation is subject to a
wide spectrum of possible interpretations, none of which
seem to be decisively excluded by the range of relevant data
which is presently at our disposal." <Derwing, 1970, p. 82>

> perception.... Indeed, it could be argued that
> natural languages can be learned initially only
> because their organization corresponds (at least
> in the simple cases) to the perceptual
> organization of the referential field. <p. 154>

Whether the LAD be innate, or learned in the

prelinguistic psycho-motor stage <Flavell, 1963>, the human

child possesses the necessary tools which enable him to

learn to use language to communicate with other people. The

cognitive structures which may still be undeveloped would

limit what the child is capable of learning. If we accept

the hypothesis that the LAD, or process itself, is modified

with experiencial feedback, as the language itself changes,

we have the beginning of a viable theory of learning in

general.[3]

2.1.2 The Linguistic Environment

The question arises as to the type of speech which

enables a child to learn to understand the language. The

child, under normal circumstances, receives a noisy input,

full of inconsistencies, incorrect grammar, and make-believe

words such as the French "dodo". Often a parent attempts to

----

[3] "...it is maintained that as new structures are obtained,
the actual learning mechanism is altered...." <Reeker,
1974, p. 37>

speed up language learning through the use of "baby talk".
Extreme simplification or distortion are unnecessary to the
learning process, and possibly even a hindrance. A child
has internalized his own language system at a given time.
For him, noise will be filtered out while the useful input,
slightly beyond his present grammar, will be noticed. Those
sentences which can be mostly understood but which add
something new will provide the most useful data for
progression.[4]

Extensions of a child's speech, in which an adult fills
in the rest of the skeleton of meaning indicated by the
child, is also of questionable necessity, though few would
dispute that it helps in learning how to fully express an
idea.[5] (This does not refer to syntactic or grammatical
corrections, which have little or no value <Brown, 1973>.)

The attention and care given a child certainly
influence his acquisition <Deese, 1970>. Addressing the
child directly, especially if an important agent in

----

[4] "...what the child wants are instances of data that will
either serve to confirm (or infirm) previously acquired
constructs or are examples that will bear on the next step
in acquisition, but not evidence for constructs which the
child will not be ready to acquire until much later."
<Kelley, 1967, p. 83>
[5] "Expansions...may present suitable conditions for children
to discover the local expression of linguistic universals
and do sc in a way that imitation and practice do not."
<McNeill, 1966, p. 74>.

satisfying his wants, draws him into the center of
attention, encouraging performance. This also draws his
attention to what is intended in the way of meaning as well
as to what is being said <Richelle, 1971>.

Approval is a form of expansion and a motivation to
reinforce a well-received utterance. Since the goal of
language is to communicate, the child receives a form of
approval when he is understood. As the child meets a larger
number of people, the conditions for being understood become
more stringent and the child's idiolect must conform more
and more to the language of a larger community <Kelley,
1967>.

2.1.3 How the First Words are Acquired

The sensori-motor period provides the child with
concepts, to which he can later attach spoken input <Nelson,
1974>. The child continues to be drawn to that which is
new. This is important when learning the terms associated

with objects.[6] Movement, as well as new objects, elicits a
strong orienting response.[7] A child's attention is drawn not
to the objects involved in the action, but to the action
itself <Brown, 1973>.

Carroll <1964> lists three sequences of development:
cognitive; the capacity to discriminate and comprehend
speech; and the development of the ability to produce speech
sounds that conform more and more to adult speech. We are
interested primarily in the second sequence, but all three
are closely interrelated. As mentioned above, the cognitive
development determines which concepts can have referents,
and therefore meanings, closely associated with them.[8] The
tuning of an individual's language to that of the community
is more important in learning syntax than in learning the

---

[6] "...'even at the age of twelve to thirteen months [word-
image] connections can be formed under some conditions after
a single reinforcement. The most important condition for
developing these connections is the presence of an intense
orienting reaction to the named image, as in the case when a
new image is placed among other images whose names the child
already knows.'...." <Slobin, 1966, p. 145>
[7] "The one outstanding general characteristic of the early
words is their reference to objects and events that are
perceived in dynamic relationships: that is, actions,
sounds, transformations - in short, variation of all kinds."
<Nelson, 1974, p. 269>
[8] "...the nature of sensory-motor intelligence severely
constrains the range of relational meanings expressed,
including even the child's notions of possessive relations
between persons and objects, of attributes of objects and
his use of apparently 'experiential' verbs." <Edwards,
1974, p. 2>

first few words.

The child's first words are usually overgeneralized. Macnamara <1972> suggests that this displays the child's tendency to take short-cuts. His strategy is to associate a word naming an object with the entire object, rather than with its parts or attributes. Thus, names for entities are often learned first. Often, as in the case of "Dada" <Brown, 1973>, names refer not only to the entity, but to everything associated with it.

Once a child grasps the names of several objects exemplifying an action or a changing state, these concepts can be associated with the appropriate word. These concepts, too, are over-generalized. Slobin <1966> cites the inability to separate the spatial relation "under" from the act of placing one object beneath another.

Permanent attributes are learned last. A good reason would be the difficulty in indicating to a child something such as color, since it is taken for granted and does not elicit an orienting response. Furthermore, how can a child differentiate, without a large number of examples (and, possibly, verbal explanation as well), among such attributes as color, shape, size, etc?

2.2 A Conceptual Structure for Actions

Roger Schank is concerned with presenting a language processing model which accurately reflects human language understanding. The theory is not completely implemented, though parts of it have been programmed by Schank and his students. Schank presents a useful structure for storing an event. It is this structure which will become important to the design of a conceptual structure for VAM. The theory centers around an actor-action conceptual base and a network of concepts (not words) upon which human cognitive processes act.

The conceptual processor consists of the following components: a dictionary of possible realizates of a word; a dictionary of ACTs used in selecting a correct meaning structure within a semantic environment; conceptual expectations; a list of conceptual dependencies; and heuristics for finding the main nominal and action.

Two levels of representation are syntactically and semantically based, repectively. The sentential level deals with utterances encoded within a syntactic language structure. The conceptual level consists of conceptualizations, which are concepts plus the relations among them. It is important not to confuse conceptual with sentential structures. The conceptual structure is mapped

onto the sentential structure as a one-to-many relation. In
other words, there may be more than one sentence which
expresses the same conceptualization. There is no direct
relationship between the ACTs and verbs, either. Not every
verb of the sentential structure will be expressible as an
ACT, but may describe or modify instead. An example is the
verb, hurt, which really describes a resultant state. Also,
not every conceptual structure will be expressed verbally,
but may be understood, as in the case of the subject of an
English imperative.

Schank divides concepts into three types: nominals,
entities which can be visualized, or picture producers
(PP's); actions, which an animate object must be capable of
applying to an object (ACT's); and modifiers, which only
have meaning as Picture Aiders (PA'S) or Action Aiders
(AA's). (Schank has more recently added two additional
concept types, time and location <Schank, 1973d>.)

2.2.1 The ACTs

As cf 1973, Schank had reduced the expression of all
actions to a set of fourteen primitive actions, each having
associated actions or states which can be inferred from its
occurrence <Schank, 1973b>. He places these into four
categories: instrumental, physical, mental and global.

Instrumental ACTs include SMELL, SPEAK, LOOK-AT, and LISTEN-TO, all of whose objects (smells, sounds, physical objects, and sounds) are used as instruments of the verb. Physical ACTs require a physical object, some more stringent than others (see figure 2.1).

ACT	MEANING	OBJ REQUIREMENTS
PROPEL	to apply a force to	any object
MOVE	move a body part	bodypart
INGEST	take something inside you	any object
EXPEL	take something from inside you and force it out	previously ingested object
GRASP	to grasp	size limit

Figure 2.1: Physical ACTs

Mental ACTs are CONC, meaning to focus attention or perform a mental process on, and whose object is not a concept, but a conceptualization; MTRANS, which describes a change in the mental control of conceptualizations to and from the conscious mind; and MBUILD, to build an internal thought combination.

The global ACTs are PTRANS, involving a change in the
physical locations of an object, and ATRANS, indicating a
change in cwnership.

The verb-ACT dictionary itself is a list of conceptual
structures associated with each syntactic and semantic
environment a word can have. Each dictionary entry lists
each possible structure for a word, indicating the slots to
be filled for each word sense.

2.2.2 Conceptual Dependencies

The conceptual structures indicate the conceptual
dependencies and can be illustrated through the use of
links. The dependencies are recognizable as the condition
where the dependent item predicts the existence of the
governing one. There are basically two types of links,
relation (figure 2.2) and case (figure 2.3), corresponding
to two levels of hierarchy:

> ...what makes a relation different from a
> case....is that a case is part of an underlying
> ACT and is predicted by that ACT. A relation is a
> rule for connecting different conceptualizations.
> Thus, relations serve as connectors within a
> memory whereas other types of dependency connect
> things within a conceptualization. <Schank,
> 1973b, p. 205>.

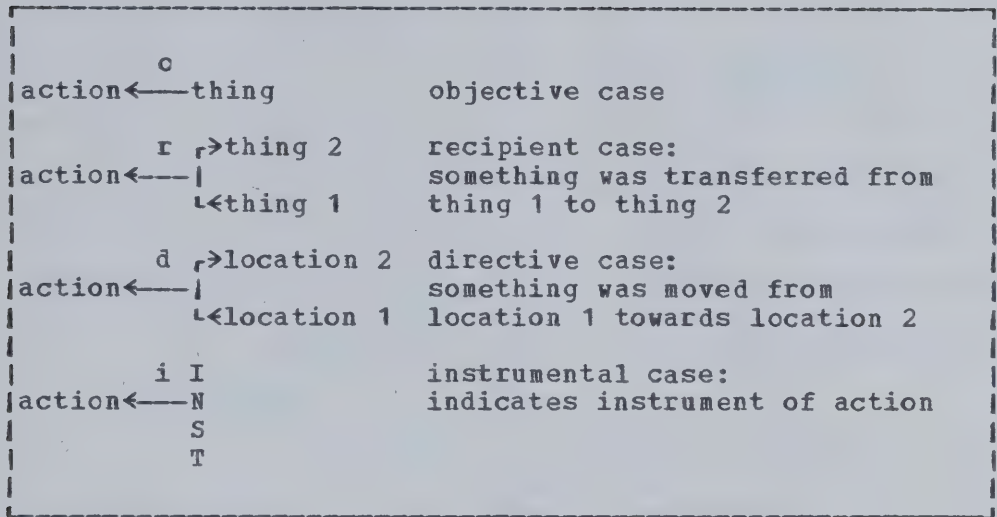

Figure 2.3: Case Links

2.2.3 Evidence in Support of Conceptual Structures

In a 1973 study, Schank <1973a> shows evidence which
indicates that, if the Conceptual Dependency theory is
assumed to be a reasonable model for conceptual structures
underlying natural language, such structures are nearly
completely formed before spoken language is present in the
child. He asserts, furthermore, that such structures form
the basis for language learning when it takes place.

```
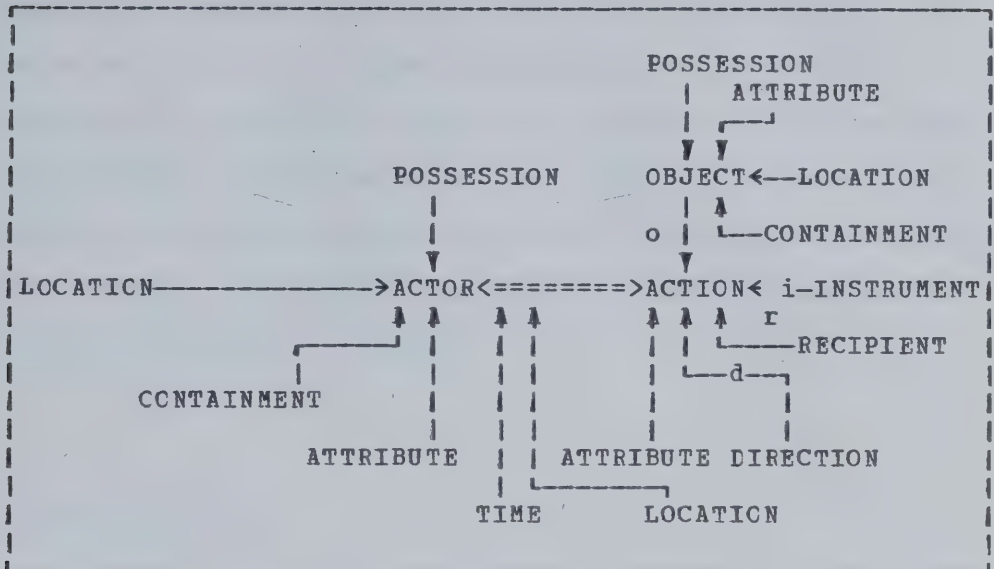

Figure 2.4: Possible Components of Schank's Actor-Action
Conceptualization
(My Diagram)

   This conclusion was drawn from experiments with two
children of ages 0-1 and 2.2-2.4, respectively. For the
older child, utterances were used as evidence that certain
ACTS, cases and relations were present in the intended
meaning. The younger child, Schank's daughter, Hana, was
observed closely for demonstration of the _intention_ to
perform an action. Care was taken to differentiate between
a simple action and the planning which indicates an
understanding of the action as a concept. Schank concludes
that, by age 1, Hana was aware of all ACTS but EXPEL, SMELL,
MBUILD, and CONC.

   It is emphasized that this study was not intended to

justify the psychological validity of the Conceptual
Dependency theory. It does indicate which conceptual
structures a child might have internalized at the time she
first begins to use language. Of course, a child begins
understanding before speaking, so the beginning of language
learning may occur simultaneously with the learning of
concepts in the environment.

2.3 Missing Parts

From the information presented in this chapter, it
should be clear that more needs to be known in the area of
human language acquisition before the process can be
modelled. Kelley <1967> outlines areas for research:

    1. Techniques need to be developed for
    interpreting which functional relations are being
    expressed in child speech.

    2. We need to establish how a child's speech
    develops over time.

    3. Finally, we need to establish which
    developmental sequences, if any, are invariant
    over all languages.

Further areas should become evident over the next two
chapters, some of which will be discussed in depth. In a
child's environment, what is the role of attention and
salience in the ability to learn to communicate associated
concepts? It appears likely that there are levels of

attention which help determine the probability of learning the corresponding word or words. If a concept appears more often in the environment, maybe it is more likely to be noticed than those appearing only once; on the other hand, if it is novel, its importance would be greater to the child than concepts with which he is familiar. Those concepts drawn into the child's focus of attention are those most likely to be associated with co-occurring words.

To determine many of these answers, the emphasis of research needs to be on relating form to meaning, rather than on relating forms to each other <McMaster, 1975>.

2.4 Criteria for a Model

With so many gaps in our understanding of human language acquisition, what can the computer model builder hope to accomplish? A criterion, which seems basic to the definition of "model" is that it perform like a child <Schwarcz, 1967>. More specifically, we feel it should have the following features:

1. Realistic input. i.e., it must not require correct parses or expansions.

2. A realistic environment for reference.

3. Some progression with maturity, whether it be a mere dependence on previous accomplishments, or an imposed maturing process accompanied by the emergence of cognitive capabilities.

With child-like performance as the overall goal, equally
suitable lists of alternative objectives could be developed.

Computer modelling, by its nature, imposes restrictions
on the nature of the linguistic and conceptual environments
and of the Language Acquisition Device. The sophistication
of equipment available and the operating system for
implementation limit the model to less ambitious projects
than brain simulation. For instance, the linguistic input
at present cannot be aurally perceived, but must be input
orthographically.[9] Furthermore, only one type of input may
be received at a time, so that an utterance and an event
cannot take place simultaneously (though we can handle them
as if they co-occurred). There are no accompanying
gestures, pitch modulations, pauses, or emotions other than
goals or desires built in to the program.

The non-linguistic environment can be input as
artificial "vision", consisting of a camera for a robot, a
display screen, or a description of positions in three-
dimensional space.

The cognition of the computer does not approach the
complexity of the human brain, nor are the processes carried

---

[9] The work of Miller <1974> does indicate a future solution
to this problem.

out in a like manner. Experience, for practical purposes, must be artificially stored in the model. The LAD, too, must be built-in, rather than learned. It should include any concept the programmer wishes the system to learn to recognize.

On the basis of Schwarcz's <1967> proposal for an acquisition component in a language model, McMaster <1975> develops a Comprehensive Language Acquisition Program. This system is the framework for the development of a Verbal Acquisition Module.

Schwarcz <1967> proposes that such a model follow an order of stages which consist of 1) recognizing sounds as lexical items, 2) associating such items with referents, 3) linear ordering, 4) generalization into classes, and 5) learning equivalent modes of expression.

In the following chapter, acquisition systems will be examined against the above criteria. Work along the lines of verb processing and acquisition will be incorporated, as needed, in the development of the component, VAM, which learns to associate the first action concepts with their lexical representations.

3

COMPUTERS AND NATURAL LANGUAGE

Natural language, for our purposes, is a dialect of English, although we hope the application could include any language used for human communication. Ambiguities, abstractions, untruths, conjectures, and idioms challenge one to imitate on a machine a process resembling language understanding. Even more difficult is simulating the development of the abilities to use language to interpret speech and to communicate ideas.

Psychological theory has no complete explanation for what happens when a person interprets an utterance, much less how he becomes capable of deriving an appropriate interpretation of the intended meaning from the verbal input. Neither has linguistic theory accounted for the development of the relationship between meaning and structure. Computer science has had only modest success in the area of explicating the acquisition phencmenon. McMaster <1975> is the first to have outlined a truly

28

comprehensive acquisition model. Other attempts have been
made, the more important of which will be reviewed here.
Their main problems were concentration on a single aspect of
language learning and lack of enough realism to make them
impressive simulations of any human process <see McMaster,
1975, chapter 3>.

3.1 Other Models of Language Acquisition

     McMaster <1975> and McMaster, et. al., <1976> review
prior models in preparation for the presentation of CLAP.
Dependency analysis and Jordan's <1972> MEchanical
Translator and Question Answerer were both discussed in
terms of their contributions and inadequacies, and will not
be covered here. On the other hand, Kelley <1967> and
Harris <1972> have both made rather significant steps in the
right direction and, therefore, deserve special
consideration. In addition, the robots of D. Block,
et. al. <1975>, and Reeker <1974> deserve mention as new
developments in this area.

3.1.1 Language Acquisition by Hypothesis Testing

     Kelley <1967> attempts to propose a realistic model of
language learning which emphasizes the learning of syntactic

structures.   The model is based on the theory that

> 1.   Syntactic acquisition is based on the child's
> comprehension process.
>
> 2.   Hypothesis-testing is the mechanism for
> syntactic acquisition.
>
> 3.   Semantics is central to syntactic acquisition.
>
> 4.   Only meaningful sentences provide data in
> acquiring syntactic competence.   <Kelley, 1967,
> pp. 148-149>

As we shall see below, we can accept all but the second

point of his theory.   Kelley's notion of hypothesis testing

is a questionable part of language acquisition.   Sentences

which are unacceptable as syntactic data (point 4 above) are

those which are radically ungrammatical or so complex that

the model cannot at least partially interpret the sentence.

Input data in Kelley's system is a set of sample

sentences generated by the system itself from a phrase

structure grammar.   The system has access, through the

comparator component, to the correct interpretation <see

Figure 3.1>, which is the parse.   The system does not label

selectional restrictions, so it is unable to learn such

semantic features as +/- animate.

The model tests two kinds of hypotheses: initial and

generated.   The initial hypotheses are programmed to

correspond to the three acquisition stages described below.

Hypotheses about lexical categories are used to classify words by semantic definitions of categories. Hypotheses about funtional relationships include a semantic definition of the relationship and knowledge of which other relationships are required in the presence of the functional relationship. These relations are used to interpret the sentence.

In generating hypotheses, the system singles out possibly important properties as candidates. If possible, data is gathered to support an hypothesis. Otherwise, the hypothesis will atrophy out of the system from lack of use.

A developmental time scale determines when successive stages will be initiated. Each such stage generates a different set of initial hypotheses to be tested against sentences <see Figure 3.1>. Once an hypothesis is sufficiently well-confirmed, it is considered to be an acquired grammatical construct.

Stage I hypothesizes only that a single word will refer to a concrete reference and be placed in the "thing" category. In Stage II, "things" and "actions" are separate categories. Functionally, a reference will consist of the "concrete referent" plus "modifier of sentence". The system generates its own hypotheses about the order of funtional relations and which categories can serve in which relation.

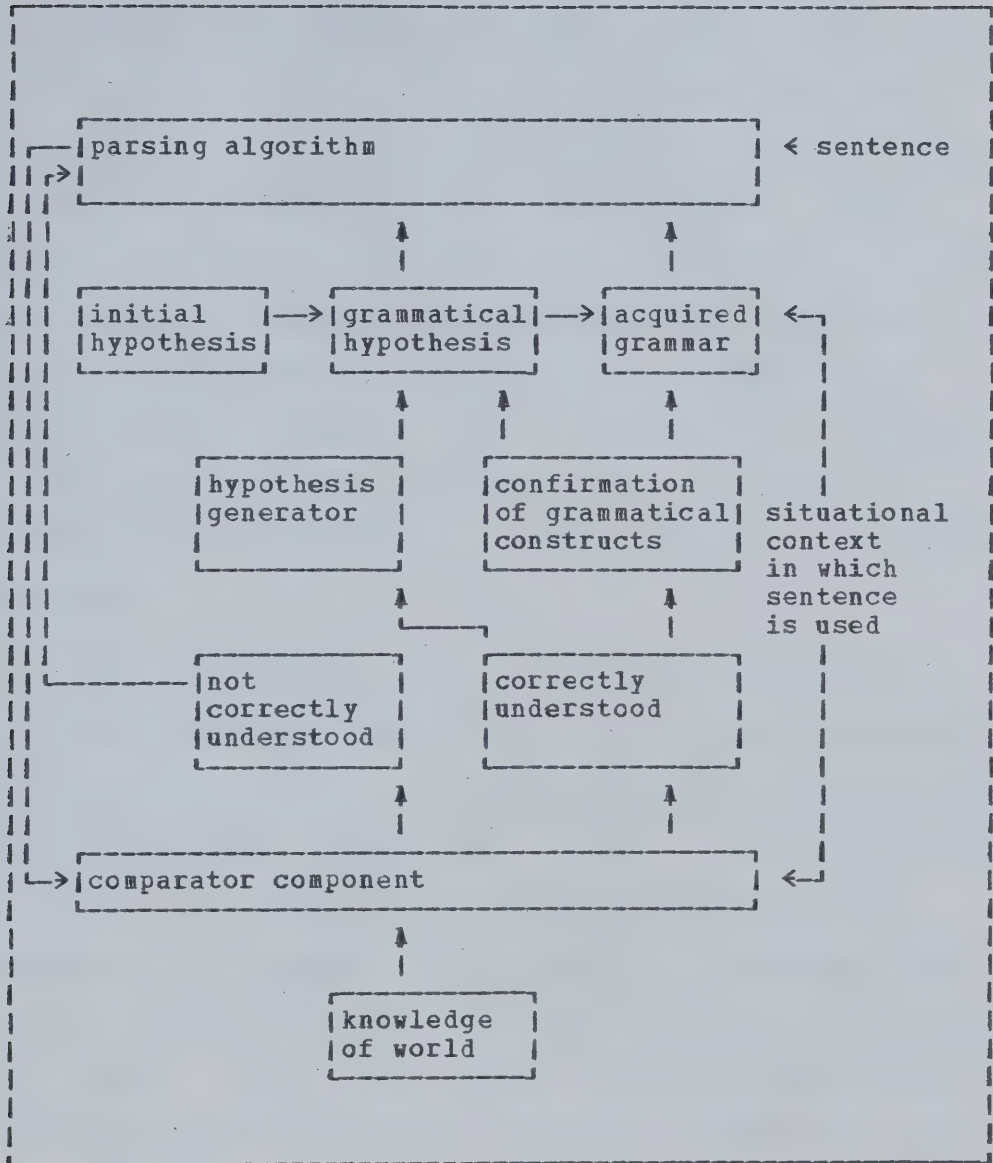

```

Figure 3.1: Flow Design of Kelley's Language Acquisition
Model
<Kelley, 1967, p. 92>

Stage III introduces a new functional relation: subject-of-
sentence.

Each sentence which is produced is input tc the parsing algorithm, which uses a context-free grammar, ccnsisting of some acquired and some hypothetical rules, and gives either a partial or complete analysis of the sentence. Kelley reasons that children also skip over non-understood parts of sentences and attempt to understand the rest. Concurrent with each stage, the system generates hypotheses to be tested against the input. From the string and the current hypothesis, the parsing algcrithm produces a labelled bracketing with identification of the appropriate functional relations.

These analyses are given to the comparator component in an order depending on the amount of the sentence understood. This component determines whether an analysis is consistent with the knowledge of the wcrld. If it is not, the parse is discarded. Otherwise, it is correctly understood and confirmation of grammatical constructs and hypotheses used is incremented. Possibly other hypotheses may be generated as a result. Later, when the model gains more confidence, it may question the validity of the input rather than its own processing.

At the psychological level, Kelley claims, this component matches hypothesized interpretations to the knowledge of the world and the situational context.

However, at the computational level, because there is no "world" available to the system, the structural description is compared to the correct parse formed when the sentence was generated. This assumption greatly weakens the realism of Kelley's system. A child's knowledge of the world bears little, if any, resemblance to a parse of a sentence identifying the grammatical function of each word. The built-in knowledge of the world unrealistically imposes syntactic categories which may be nonexistent in the absence of language.

There is a maturing effect in Kelley's model, but the effects seem to be predetermined rather than allowed to result from changes which are built into the language of the previous stage. A stage should be dependent only upon conceptual growth and prior linguistic ability. In Kelley's model, each stage is associated with a specific hypothesis. Even if one were to give credibility to hypothesis-testing as a legitimate factor in human language acquisition, it is perhaps somewhat hasty to pre-determine the content and the order of these postulates.

In terms of a model, Kelley's system incorporates the environment, which is a necessary component. But he fails to implement a reasonable facsimile of one. His idea of partial understanding of a sentence providing useful data is quite reasonable and worthy of inclusion in any model

definition.

3.1.2 A General Problem Solving Model Applied to Natural Language Acquisition

An adaptive problem-solving model proposed by Harris <1972> employs an objective function as success criterion, an adaptive routine which generates strategies, and strategy testing routines. The objective function rates strategies on their ability to perform some desired task by using them in test situations.

Harris programmed his problem-solver using language acquisition as an example. As the robot moves, the teacher describes the action. The input is a sort of baby talk skeleton, consisting of those words which the robot can map onto concepts of its own mental and physical capabilities. If more than one word is needed to represent an idiomatic concept, the word group is connected by underline characters.

In Phase I, Harris inputs a list of words and a list of their respective concepts. A table of cross-correlations determines the probability that a word matches a particular concept. If the jth concept and the ith word are part of the action and input, respectively, the correlation is

increased. If either the word or concept, but not both,
appears, the correlation is decreased. The function Harris
uses to determine correlation is based on the previous
correlation, a bias (z) equal to + or -1, and m, which is
related to the iteration, n, as follows:

$$m = \begin{cases} 16, & n < 32 \\ 32, & 32 \leq n < 64 \\ 64, & 64 \leq n < 128 \\ 128, & 128 \leq n < 256 \\ 256, & 256 \leq n \end{cases}$$

Harris finds the following formula, adapted from Samuel's
checker playing program, a useful correlation measure:

$$c(n+1) = c(n)(1 - 1/m) + 1/mz$$

In Phase II, English sentences are mapped onto parts of
speech. The strategy is to produce a transformational,
context-free grammar with the aid of operators which suggest
good grammars.

Harris does not meet the first criterion for a language
model (set forth in section 2.4) because his input is
unrealistic. During Phase I, the input word-concept pair
are valid only on the assumption that the child concentrates
on the correct concept in the environment, which one cannot
assume. For instance, a child would probably not be able to
correctly associate the word "paw" when an adult indicates a
cat to him. Even the word "cat" would not necessarily refer
to only a cat nor to the entire cat.

Another unrealistic aspect of the input is over-simplified sentences, which seldom contribute to a child's progressional data <Kelley, 1967>. Underlining multi-word concepts, on the other hand, seems no more unrealistic than segmenting the string into words.

This model has made some progress in equating a concept with something other than an arbitrary internal structure. The robot's physical and mental capabilities are programs as well as concepts, providing the environment specified in the second criterion. These processes are pre-divided into part of speech classes, which presupposes a linguistic categorical knowledge prior to linguistic experience.

The model's linguistic ability is progressive in that word associations are made before grammar-learning is attempted, although there is no reason the two processes could not co-occur. Beyond this, Harris has not developed progressive strategies, so the third criterion is also unrealized.

Since the goal of Harris's model was to test a general adaptive problem-solving model, it is easy to understand why the language acquisition process is not very close to human acquisition.

3.1.3 Deep Structures as Card Configurations

By stating explicitly that their system is designed for
a robot and not as a model of human behavior, Block et. al.
<1975> avoid any direct comparisons of this acquisition
method with the steps by which a human acquires a first
language. Nevertheless, Block provides certain restrictions
in his model which are necessary for a realistic learning
environment.

The robot is assumed to combine up-to-date features of
a mobile automaton and the Stanford/MIT hand-and-eye robots.
The environment is a giant chessboard room about which the
teacher and robot converse via Teletype. The robot's
learning of syntax is dependent on four conditions:

    1. An environment to provide something to
    converse about.

    2. A linguistically competent teacher to provide
    linguistic input about the environment and to
    accept or reject the robot's trial utterances.

    3. The robot must have some lexemes associated
    with concepts.

    4. The robot must be able to learn that the co-
    occurrence of lexemes can express a relation
    between the concepts they represent <Block,
    et. al., 1975, p. 579>.

The robot, with no pre-programmed linguistic
information, but with an environment and a linguistically
competent teacher providing feedback, can theoretically

acquire considerable linguistic competence. The three types
of information it must learn are lexical, syntactic, and
pragmatic. Some lexical knowledge must precede syntax
acquisition.[1] Pragmatic information is basically non-
linguistic.

Lexical information consists of connections between
lexicons and entities, attributes, relationships, or
actions. The strength or weakness of these connections can
most efficiently result from teacher feedback. This, as we
discussed earlier, is unnecessary in children, although it
may be helpful. Certainly, some form of input is required
from some competent language user.

The system consists of 4 components: a World Map, which
is a four-dimensional representation of a chess-board
environment; the Associator, which combines, gates, and
passes on information from other components; the Dictionary,
which consists of storage bins connected to a teletype and
the Associator; and a Syntax Crystal, which results from the
learning algorithm. This component allows the recognition
of constituent and dependency relationships, distinguishes

----

[1] "One must be able to at least partly understand a string
independent of [syntactic] characteristics to recognize that
it is a string. Only then can the syntactic characteristics
of such a string be acquired." <Block, et. al., 1975,
p. 579>

the correct form in parsings of syntactically ambiguous sentences, and portrays the similarities between the constituent relations of paraphrases.

Lexemes with purely syntactic roles cannot be applied to perceptual or World Map data, but rather to relationships among other lexemes. To simplify the process, Block chose not to classify such relations, but to acknowledge only their existence. The Syntax Crystal is the mechanism by which the robot learns to use relational information.

To produce a sentence, the robot selects the morphemes associated with the meaning it wishes to express, and attaches structure cards. To parse a sentence, the lexemes are placed in the order they appear, while the structure cards are added to yield the conceptual relations.

The robot first associates two lexical concepts which co-occur by using two connector cards placed above two non-connected co-occurring lexemes. More cards are added to basic structures by considering the basic structure as a unit to be connected similarly to a third. Though it is not clear how it is accomplished, the authors state that, in the case of "big robot goes", the robot will connect big to robot, then connect this structure to goes. The rectangular cards must remain all in the same direction for making connections.

If substitutions are acceptable, the new lexeme is given the same edge codes as the replaced one; otherwise, a new top code must be generated. The building of additional codes and optical codes allow the development of syntactic categories.

The instructor feedback appears to be a mere expedient to the learning algorithm. On the other hand, the necessity of a linguistically competent teacher to the syntax acquisition would imply that the model is not realistic. A child would not receive syntactic correction under normal circumstances, and seldom would have a "linguistically competent" teacher. Also, by taking into consideration only English, the authors run the risk of imposing non-universality on their model.

This approach does attempt to operate without pre-programmed syntactic categories, to develop a basic lexicon as a prerequisite to syntax acquisition, and to learn through environmental interaction the meaning attached to the corresponding language. All of these aspects are commendable, and all are incorporated in CLAP, which is described in section 3.2.

3.1.4 Another Problem-Solving Robot

Based upon the Newell, Shaw, and Simon GPS (General Problem Solver), Reeker <1974> proposes a theory of syntactic acquisition. Other than providing an excellent review of the state of the art, the contribution of this work is difficult to assess, especially in light of Harris' prior research. The language is oriented around existing linguistic theory, as are the ideas and diagrams of syntax. It was difficult to find some common ground for comparison with other acquisition systems reviewed.

The proposed PST (Problem-Solving Theory) assumes the goal to be competence, and imitation to be a major motivation. Quite significant is the idea that perception provides reinforcement for the language behavior. The theory is interesting, but means of implementation do not go beyond GPS as it exists.

The work, in general, was of little relevance, since our effort centers around the initial stages of acquisition, which are omitted entirely by a model which begins at syntactic acquisition.

3.2 CLAP

McMaster's <1975> comprehensive language model receives orthographic input from a terminal, as well as input from an

environment. If the environment is a CRT screen, it can be
pointed to, windowed, moved, and transformed by either a
human or CLAP. No correct parses are input. Utterances are
not necessarily simplified to match CLAP's progress.

3.2.1 Components of the System

Linguistic input to CLAP <see Figure 3.2> is in the
form of natural adult speech (u), not geared to CLAP's
acquisition stage. The non-linguistic input (r,a,s) is
natural, within the limits of the environment, rather than
artificially constrained for easier learning. Finally,
there is no explicit feedback except, during the latter
strategies, approval or disapproval and non-linguistic
input. At an even later time, linguistic responses will
facilitate additional learning.

Both the Parser and the Responder are control
structures which may be described as Augmented Transition
Networks (ATN's).[2] Each arc of the ATN is labelled with an
input, a process, and a weight. Each arc's condition is

----

[2] "A <u>recursive</u> <u>transition</u> <u>network</u> is a directed graph with
labeled states and arcs, a distinguished state called the
start state, and a distinguished set of states called final
states." <Woods, 1970, p. 591>. The network is augmented
to provide an arbitrary condition on each arc to be met
before the arc is followed.
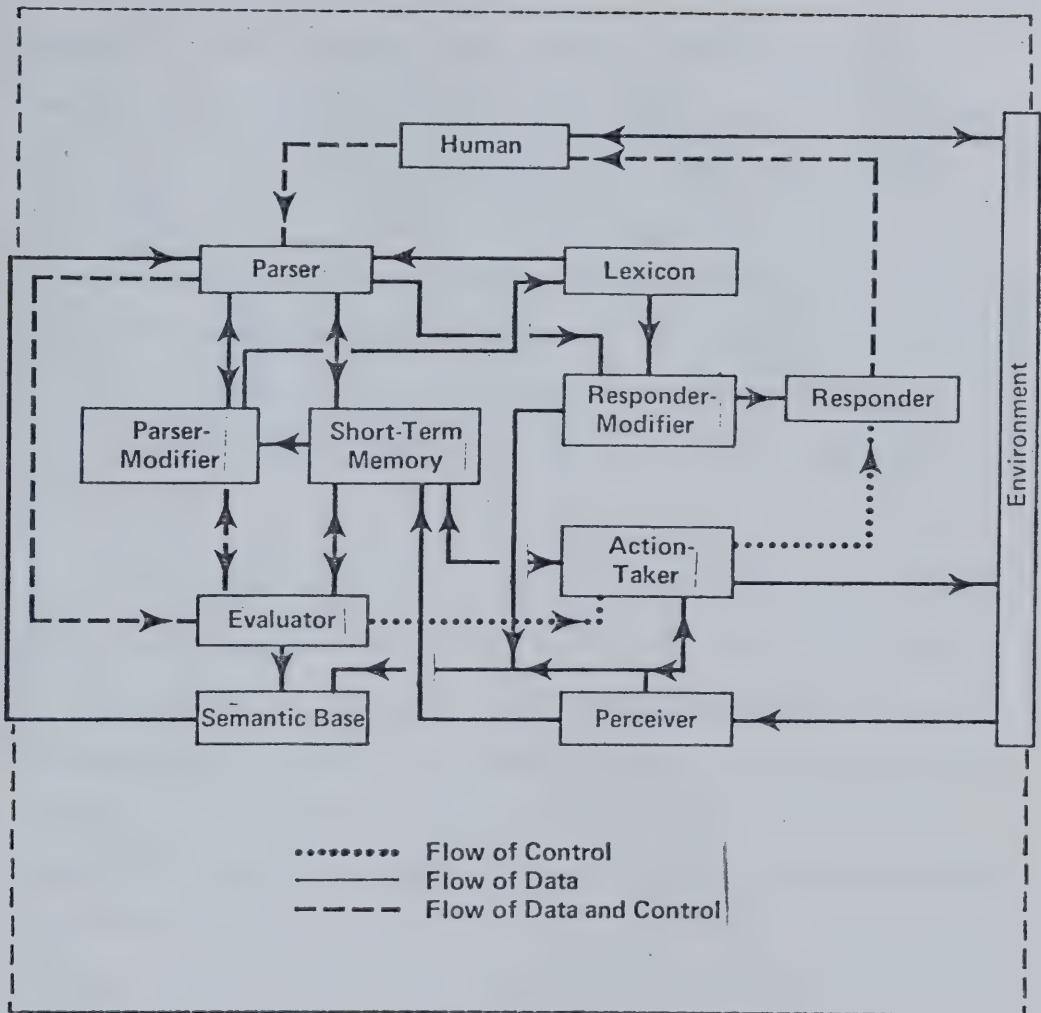

Figure 3.2: Components of CLAP

weighted so that the most highly weighted arc emanating from
a state will be chosen. The arc's associated process is
executed and the state at the end of the arc becomes the
next state of the component.

An input on a Parser arc may be a segment, a branch to
a sub-ATN, or a set of conditions on the attributes of the

meaning of the current input segment. This process is a
semantic structure or frame. The Parser uses the Lexicon
and the set of Focal Structures from Short Term Memory
(hereafter referred to as STM) to segment incoming
utterances and produce parses. The Evaluator takes this
Parse and assesses its credibility. From this evaluation,
the Parser-Modifier uses the Parse and Focal Structures in
STM to change the Parser's weights, which are conditions on
the arcs.

The Responder attempts to construct an output string
from the Intention of the Action-Taker. This utterance is
an ordered set of lexical items representing the Intention.
The Responder's arcs are labelled with 1) a pointer to an
element of the Semantic Base, 2) a pointer to a sub-ATN
which references an element in the Semantic Base (which may
be thought of as inputs), or 3) a pointer to a lexical item
or items (which may be null) as an output <McMaster, 1975,
p. 126, p. 128>.

The Responder-Modifier changes the Responder in much
the same way the Parser-Modifier alters the Parser. This
component uses both the Parser and the Lexicon to add to the
structures in the Responder and to modify its weights. It
examines the Lexicon and, for each concept in the Semantic
Base, it attaches the lexical item for which it is a clear-
cut meaning. The weight is kept close to the segment

concept weight.

The Responder-Modifier also takes the inputs and
processes which label the Parser arcs and translates them
into semantic conditions and graphemic outputs labelling
arcs on the Responder. The semantic condition is a pattern-
matching routine which tries to find the structure of the
Intention. The output is zero or more segments.

Many details for this process are missing, including
algorithms for traversing the Parser and selecting arcs, but
McMaster does enumerate the possible input-to-output
translations.

McMaster believes the child neither makes nor tests
syntactic hypotheses <McMaster, 1975, p. 134>, but instead
attempts to create more complex rules for deriving sense
from an utterance. Generalization occurs when the
conditions of the rule can be met by a new utterance as
well.

The Action-Taker can change the environment, add
information to the Semantic Base, or respond to the Human's
input by producing the Intention, from which the Responder
attempts to build an output string.

The Perceiver, as the name implies, registers
environmental changes and stores events in STM. It can also

change the Semantic Base if necessary.

The suggested implementation is a three-dimensional CRT
representation which should be rich enough to induce many
processes of language acquisition. The more complex the
environment is, the greater the concern with whether to
explicitly represent relations in the Semantic Base or to
generate them as part of the Focal Structure. Winograd's
BLOCKS world explicitly represents some, while others are
generated in goal-seeking. For CLAP, relations must be
explicitly represented, at least in the Focal Structure.

The Semantic Base is the essential interface between
the Human and CLAP. It is the BLOCKS world, structurally
represented in a uniform way for actions, inferences,
events, etc., allowing uniform learning procedures to be
used by the Parser-Modifier. The STM contains an event
list, which includes information as to Parses, Responses,
Foci, and Human non-linguistic input at the occurrence of
each.

3.2.2 The Learning Strategies

Rather than emphasizing production, McMaster chooses to
consider the strategies which are applied to comprehension
aspects of the acquisition problem. The building of the

Parser is the governing function of CLAP's acquisition
process. Production is simply a result of structures built
in the Parser <McMaster, et. al., 1976>. CLAP does not have
the complication of cognitive development found in children,
so the strategies are admittedly an oversimplification of
human acquisition strategies. During the first strategies,
word-concept associations develop as links which have
weights indicating the probability that the link is correct.
McMaster explains the first twc strategies in some detail,
while the last three are left relatively nonspecific <King,
et. al., 1976>.

3.2.2.1 Strategy 1: Segmentation and Meaning Association

      Strategy 1 involves the establishment of weighted links
between the lexical items and the Semantic Base. At first,
lexical items may include many incorrectly-segmented
morphemes which eventually atrophy out of existence.
Weights between these segments and the concepts help
determine the most likely parse.

      As a child learns to recognize repeated chunks of the
input stream through the recognition cf morphophonemic
boundaries, CLAP must learn to recognize morphographemic
bounds. Parsing in Strategy 1 consists of breaking the
input into meaningful segments <See Figure 3.3>. At first

the input is segmented into single characters by that part of the Parser called the Segmenter. The Parser-Modifier then creates a new segment from each pair of adjacent segments. The Parser then attaches pointers from each of these segments to each concept associated with the focal region. Depending on the sophistication of the Semantic Base, these may include concrete referents, classes and relations, cognitive competence, and the ability of the system to affect the world.

The establishment of segment-concept links is used for generating future parses. The Evaluator compares the interpretation, based on concepts in the focus, with those concepts closely linked to the input, and passes its results to the Parser-Modifier. The weight will be lowered if the focus does not include a particular concept. Otherwise, association proceeds as before. Again, the Parser-Modifier attempts to join adjacent segments to add to the lexicon.
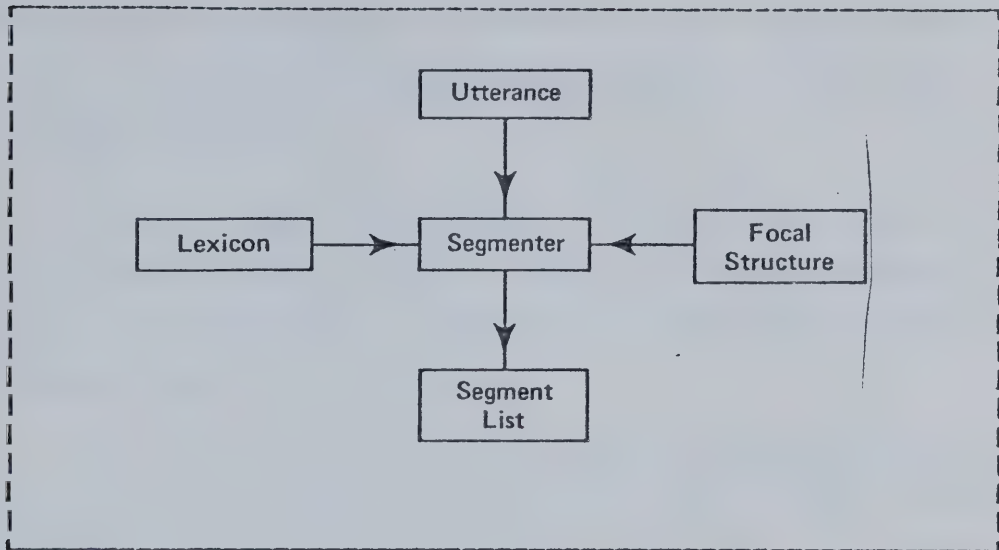

Figure 3.3: Parsing in Strategy 1
<McMaster, 1975, p. 98>

The Action-Taker's activity depends on the input.
CLAP's global goals are to accumulate knowledge, to
communicate its knowledge to the human, and to receive
approval. Therefore, CLAP looks for something it can add to
its Semantic Base, something indicating a desire for CLAP's
knowledge, or something indicating approval. If it
recognizes, in the list of concepts expressed in the input
utterance, any completely specified procedure, the Action-
Taker may evoke that procedure. During Strategy 1, it
cannot add to the Semantic Base because the concepts are not
specifically related. Likewise, it cannot yet respond.

If an action is input, the Action-Taker can select part
of its conceptual structure, attempting to respond by

outputting a list of those concepts it can map onto lexical
items. Here lies the correspondence with a child's first
one-word utterances.

In the case of disapproval, the Action-Taker looks to
its previous output, stored in STM. It can diminish the
weights on links between words and concepts, depending on
its confidence in those links.

If a sentence is input, the Action-Taker responds as in
the case of an action, except that it must use some
heuristic to determine the Focal Structure.

During Strategy 1, then, CLAP associates concepts with
input strings while learning to distinguish, within the
linguistic context, those strings with associated concepts.

3.2.2.2 Strategy 2: Linear Ordering

As soon as the Lexicon has developed to the stage
where CLAP can understand more than one word
(segment) in an incoming utterance it can begin to
attach import to word order. However,...Strategy
2 is really concerned with building structures
from a few morphemes. <McMaster, 1975, p. 104>.

The building blocks of the future Parser are weighted
segment-concept links established during Strategy 1, and the
Structure Builder, an ATN built by Strategy 2. This is the

first time CLAP begins to use an ATN.

The Segmenter continues as in Strategy 1. The
Concentrator examines the Lexicon, Segment List, and Focal
Structure to produce a Target Structure, the smallest and
most highly weighted semantic structure which both appears
in the Focal Structure and contains all concepts associated
with segments in the Segment List. The Parser-Modifier
builds the first of the future Parser by examining the
Target Structure and building a network which accepts the
Segment List and outputs the Target Structure. Each arc in
the network is weighted so as to indicate the subjective
probability that it is the correct arc to follow in a
particular situation to produce the desired Target
Structure.

With natural input, there will always be some words
which have no direct referent in the environment, yet change
the meaning of an utterance, their own meaning lying within
the relationships of the referents. McMaster suggests ways
of handling these morphemes during this strategy, but this
will not be discussed here.

3.2.2.3 Strategy 3: Structural Generalization

Generalization is required to make the parser efficient

and to generate novel utterances. It also helps organize
the parser. Similar semantic and syntactic processes which
label the nodes of the Parser can be combined into a single
label and process. The old arcs, if not used, will age
their way out of the Parser. Likewise, faulty
generalizations, lacking confirmation, would eventually be
discarded.

McMaster defines three types of generalization which
might be useful in implementing Strategy 3. Generalizations
are based on the structure of the Parser, and directed by
semantic regularities and processes which label the arcs.
These are only suggested guidelines and are not a strict
specification of this strategy.

Semantic generalization (Strategy 3.1) involves the
regularity of semantic characteristics on the arc labels.
For instance, if two or more processes on two or more arcs
require filling a slot with distinct concepts which share
attributes or values at some level, new arcs are created to
parallel the old ones, which generalize the process. The
new inputs resemble feature-matching procedures.

For instance, suppose two arcs have the inputs I(1) =
B6 and I(2) = p1, and corresponding processes P(1) = "insert
:B6 in *3" and P(2) = "insert :P1 in *3". (B6 and P1 are
lexical items; :B6 and :P1 are concepts; and *3 is a slot in

the predication). Since both :P1 and :B6 belong to the
class of entities called #THING, this is the condition
placed on the new, generalized arc, which must be met before
the arc can be followed.

Strategy 3.2 is what McMaster calls syntactic
generalization. This reorganization of the Parser is on the
basis of topologically similar structures occurring in
sequence. In the case where two arcs have similar inputs
and the same procedure, recursion is introduced. This
allows such occurrences as an unlimited number of modifiers.
Strategy 3.2 would necessarily follow the semantic
generalization of Strategy 3.1, because there would seldom
be instances of the same lexical item appearing twice in
succession.

Strategy 3.3 generalizes congruent parts of an ATN,
causing the new arc inputs to be a sub-ATN which generalizes
the previous structure-building operations. An instance of
this would be the occurrence of a prepositional phrase in
various parts of the sentence.

3.2.2.4 Strategy 4: Conflict Resolution

Occasionally, discrepancies between the interpretation
of the utterance and the environment cause noisy input to

the system. Eventually, problems of interpreting such
conflicts as lying, hypothesizing, making negative
statements which are true about the environment, requesting
information in a statement form, and commands to change the
current situation, must all be linguistically mastered or
they will confuse the system.

Even a child will be confused when presented with a
large number of untruths. This must be avoided in CLAP. To
overcome the other difficulties, the Evaluator can, by some
heuristic, either build a hypothetical world, negate the
parse, hand the parse to the Action Taker, or, if there is
no direct contradiction, adjust the Semantic Base to agree
with the parse.

3.2.2.5 Strategy 5: Using Discourse

McMaster has very little to say on this subject. It is
not clearly understood how humans employ such complicated
processes as anaphora, quantification, hypothetical worlds,
and referential ambiguity in daily discourse.

The usual area of concentration in mechanical language
systems is the sentence. Wilks <1973a> enlarges his context
to the paragraph, but humans can connect ideas far beyond
that limit.

This strategy requires the parse to supplement or replace the Focus. In responding, CLAP's Responder accepts the Intention of the Action Taker and attempts to produce an utterance.

3.2.3 Evaluation

CLAP represents a step towards the realization of a language acquisition system which is both realistic (the major goal set forth in Chapter 2) and programmable. The major drawback to using CLAP as a model is the lack of necessary detail for implementation, especially in the later Strategies.

The fact that CLAP uses graphic input seems analogous enough to the input of speech, fulfilling the requirement of realistic input. Although graphic input lacks cues often provided by vocal inflections and stress, it has not been established how important these factors are in the learning of segmentation, because languages vary in the extent to which such cues convey meaningful hints. An advantage of the graphic input is the limited number of primitive symbols an alphabet has, as opposed to the large number of phones in a human dialect.

An environment also exists for CLAP. Throughout,

McMaster suggests implementation using a SHURDLU-type BLOCKs world <Winograd, 1972> on a CRT (see figure 4.1). If the equipment were available, a robot would insure a richer environment and the ability for CLAP to conceptualize itself and its processes as part of the environment.

The strategies provide a means of designating CLAP's progress, although there is no cognitive maturing effect beyond this domain. By avoiding the introduction of cognitive development, no unrealistic psychological progression is imposed on the system. The lack of any true cognitive development could be construed as a major weakness of CLAP. On the other hand, there could be disadvantages to implementing a dynamic maturity for CLAP, not only because of the lack of a specific model of the human processes, but because an experimental control would be lost. Assuming one of the goals of a computerized language acquisition system is to learn more about how humans acquire language, it would be advantageous to study this in the absence of maturing effects.

As far as it is specified, CLAP appears to be programmable, though it is not always efficient. The entire segmentation process suggested for CLAP stresses enumeration of all possible segments rather than the generalization noted so often in other aspects of a child's acquisition. It is interesting to consider whether children might go from

the top down, instead, placing sentences or parts thereof,
up to a certain length, into the primary lexicon, then
breaking these down by pattern-matching routines. For
instance, if "thedogisbrown" and "hownowbrowncow" were both
in the lexicon, and each pointed to the concept, :brown,
among others, a routine could generalize the situation,
using both spelling and meaning as clues, to create a new
lexical item, "brown", with pointers to all the meanings
these two sentences had in common. Faulty generalizations
would drop out from lack of use, as would those sentences
input as lexical items.

When the meaning of "brown" became established,
sentences like "hownowbrowncow" could be interpreted as two
items, "hownow*cow" and "brown". In this manner,
disconnected morphemes could be lexicalized. The Lexicon
itself could be either a separate ATN or part of the Parser.
A Lexicon-Modifier could adjust the weights on links.

Segmentation in Strategy 1 is an area in which a
significant amount of research is needed before it can be
practically implemented.

No doubt, many other problems will arise as CLAP's
Strategies are implemented, but it is hoped that the overall
approach will survive the test of applicability.

3.2.4 A Test of Plausibility

A Vocabulary Acquisition System (VAS) attempts to demonstrate, by carrying out one of the first tasks of CLAP, the feasibility of implementing CLAP. VAS attaches the meanings of concepts in a simple CRT-like BLOCKS world to descriptive words. VAS does not implement all of Strategy 1.

The VAS environment is a simple CRT-like display without the CRT. In other words, although size and position are indicated within the semantic base, there is no implementation of a display.

The internal representation is a predicate calculus notation similar to Winograd's<1972>. Each predication provides a potential insertion pattern to be an arc label on the ATN. One problem immediately following from this is the awkward manner in which the semantic base must be scanned. For instance, to display an object, :B2, which is a red cube with side 50 and located at point (100 200 200), one would need the following information or some similar representation:

```
(#AT :B2 (100 200 200))
(#SHAPE :B2 #RECTANGULAR)
(#CCLOR :B2 #RED)
(#SIZE :B2 (50 50 50))
```

In Winograd's and in McMaster's representation, one would

need to scan each list in the semantic base for those whose second element is ":B2".

A second criticism of this representation is that (#IS a b), which indicates that a belongs to the class b, superimposes a classification scheme to which a child might not have access until his language delimits such categories.

The linguistic representation, too, follows Winograd's format. Associated with each lexical entry is the indicator WORD with value (WORD) and the indicator SMNTC with the value

```
(WORD ((MEANS ((<concept><weight>)
               (<concept><weight>)
                .
                .
                .
               (<concept><weight>) ))))
```

WORD can later be the part of speech, once CLAP progresses to the point where it can differentiate them. The weights here are simply counters of the simultaneous co-occurrences of the word and the concept.

Sentences are input with complete punctuation and are pre-segmented. VAS learns no segmentation. A child's verbal input includes pauses, intonation, and gestures. The first two roughly correspond to punctuation. VAS considers only gestures like pointing in the process of determining a focus. Ideally, a sentence and a focal point in the two-

dimensional representation of the BLOCKS world would be

input. In VAS, though, only a list of objects constitutes

the preliminary focus. An initial lexicon is input with no

meanings, as there is no management scheme to delete lexical

items which have no environmental referent.

"There are three classes of predicates in the BLOCKS
world:

    1. One-place attributive predicates. For
    example, (MANIP x) attributes the property of
    manipulability to each concept in the list x.

    2. Two-place attributive predicate. For example,
    (#IS x y) attributes membership in the set
    represented by the concept y to each of the
    concepts in the list x.

    3. Relational predicate. For example, (#SUPPORT
    x y) means that the non-commutative and transitive
    relation of "supporting" exists between the object
    x and each object in the list y.

Each concept c in f is examined, and each class of

predicate is processed as follows:

    1. For each Class 1 predicate p in which c
    occurs, p is added to the focus.

    2. For Class 2 predicate p in which c appears as
    a first argument, each concept in the second
    argument is added to the focus.

    3. For each Class 3 predicate p in which c occurs
    as the first argument and one of the concepts in
    the second argument also appears in the focus, p
    is added to the focus."
            <McMaster, 1975, pp. 144-145>.

Word-concept co-occurrences are counted, the result

being stored in an i by j matrix. The number of co-
occurrences of the i'th word and the j'th concept is the
(i,j)th entry in the matrix. The total number of times a
concept c(j) has occurred, the number of occurrences of word
w(i), and the ijth entry are used to derive a weight between
the two which, assuming a larger value of the co-occurence:

1. Is small if both w(i) and c(j) have occurred
often.

2. Is also small if w(i) is seldom used while
c(j) is used frequently.

3. Is larger if w(i) occurs frequently and c(j)
does not.

4. Is largest when both w(i) and c(j) have
occurred infrequently.

If u(c) equals the number of times a concept c has appeared
in a focus, u(w) equals the number of times a word w has
been presented in the input, and u(c,w) is the number of
times a word w has appeared in the utterance at the same
time that the concept c appeared in the corresponding focus,
we can construct a function to derive the correlation
between the word and concept as follows:

$$F(u(c),\ u(w),\ u(c,w)) = u(c,w)\ (2 - u(c)m/u(w))$$

where m, whose value was chosen through experimentation, is
at present .21, with no claim to being the optimal value for
all corpora. In fact, the function of m is not understood;
it would be interesting to look into this problem.

The results of the implementation are impressive. From

a noisy input of 219 utterance/focus pairs, VAS successfully learned 9 out of 16 direct associations. With a corpus more oriented towards helping VAS learn, 18 out of 24 associations were learned with 39 (u,f) input pairs.

VAS does not learn to differentiate between two concepts which always co-occur. Children also produce such errors. VAS can also wrongly associate lexical items in the corpus whose proper concepts never appear in the focus. Such instances were due to the use of Misleading Extraneous Words, and was the fault of the noisy corpus. Finally, some concepts occurred so often that, when the correct word did occur, the Excessive Concept Usage (ECU) lowered the value of the correlation function to the extent that the correct concept was not chosen as the meaning of the word. McMaster suggests that this may be corrected by incrementing $u(c,w)$ for each time the concept appears in the focus. Another solution to ECU might be to alter the correlation function.

4

A VERBAL ACQUISITION MODULE

In spite of its shortcomings, CLAP provides the most complete framework proposed to date for an acquisition model. Until the proposed concepts have been applied, we can only speculate as to their effectiveness in the task of language acquisition. VAS made a start in the direction of implementation. It is hoped that VAM will further the completion of the first strategy, as well as reveal areas which could be reformulated.

The Verbal Acquisition Module is an attempt to overcome some of the shortcomings of VAS. Schank's conceptual representation will be adapted to the module, altered because of the limitations of the environment and needs of the module. Much of VAM's capability and methodology is identical to that of VAS. Therefore, we will emphasize the changes which have been made to accommodate acquisition of verbs in the model.

Movement in VAM's environment enriches the conceptual vocabulary beyond that of VAS. VAM either observes an action, performs an action, or, like VAS, receives as input a pointer to one or more objects. When it perceives an utterance, it compares the expanded focus (see below) with the words of the utterance, and computes a correlation between each word and concept of the inputs. The calculation of this correlation will be discussed in section 4.4.

4.1 Conceptual Structures for VAM

VAM's environment is like a CRT display of BLOCKs, as in VAS's world. Although the display is not implemented, VAM's data structures contain all the necessary information for such a display. There is no gravity, mass, or temperature in VAM's world, although there are three dimensions and a representation for color.

Since there is no CRT display to be used in pointing, windowing, and moving objects, and as the Human is imperceptible to VAM, there is no viable means of distinguishing between an action performed by VAM and one performed by the Human. The only distinction is between movements which name VAM as the agent, and watching objects change positions, as a result of action by the Human. The

only purpose of this convention is to see if VAM could learn
its name in relation to the concept of itself. Because this
is a superficial imposition on the system, in that VAM
cannot make decisions to act upon the environment, we did
not expect impressive results in this aspect, but were
somewhat surprised, as we shall discuss later.

There are nine physical objects in the environment,
each represented by a list in the semantic base, and each
having its own name. Three are cubes, two are rectangular
blocks, three are pyramids, and one is a box, capable of
containing other objects. In addition, there is VAM's arm,
a black line-shaped figure which hangs down from the top of
the scene (see figure 4.1).

As mentioned in Chapter 3, the conceptual framework of
Roger Schank provides a springboard for the development of
VAM's data structure <see Figure 2.1>. Schank's
descriptions center around events, whose structure would be
learnable by VAM only if the STM (short-term memory) were
implemented. VAM does not have access to a memory except
for the usage counts of words, concepts, and mutual
occurrences. Neither is time represented to VAM. The time
during which an event occurred could not be represented in
our drawings. Time between events was omitted because we
were not implementing short term memory in which to store an
entire event.

Figure 4.1: The environment for VAM

Instead of the representation of an event as a nodal
net structure, we will list in the focus those concepts
which would make up an event in VAM's world, including the
name of the event itself and the more primitive actions from
which it is formed. It is these events, or programs

representing various levels of structure, which actually
create the focus, as well as handling the necessary
environmental manipulations. We decided to include all
levels, including primitives, in an effort to avoid language
dependence in our representation. It is assumed that a
child at the same stage as VAM would be capable of
extracting the concepts of the action from its total
occurrence.

It will be recalled that Schank characterizes a
conceptualization as centering around an actor-action mutual
dependency, or an object-state one:

> A conceptualization consists of either an actor-
> action-object construction or an object-state
> construction. If an action is present then the
> cases of that action are always present. One case
> of an action is instrumental which is itself a
> conceptualization. <Schank, 1973b, p. 12>

Our model is concerned with the former construction, the
object-state one only performing an instrumental function
for some actor-action-object configurations.

4.1.1 Components of the Actor-Action Conceptualization

Since an action cannot occur without an actor, VAM,
being the only actor in the environment, is the only one who

can perform an action. Yet VAM has no physical
representation of itself other than its arm. VAM's arm,
which can be the actor of the instrument of the action, can
have attributes, containment and location. (Hereafter,
"attributes" will include containment and location, unless
otherwise specified.)

The time and location of a conceptualization are not
concepts to VAM, because of a lack of memory and the absence
of any other locations with which to contrast the location
of an event, which always occurs in the same CRT-screen
location.

The action itself must be limited to those primitive
actions which are relevant to VAM's viewpoint. As we shall
describe below, some of these can be broken down into a
series of actions, while some have inferences which should
be included in the focus. We also believe Schank overlooked
some primitives, so we add ACTs which could not be expressed
in terms of the fourteen primitive actions.

The ACT could have attributes, but events are
registered by VAM as discrete environmental changes, which
limit the display of attributes such as speed. Therefore,
no attributes of actions will exist in VAM's focus.

Naturally, the object of an action, as well as its
attributes, can and must be included among VAM's concepts.

An object will always have its state represented as its data structure at the occurrence of a particular event. This includes an object's attributes of size (three dimensions), whether or not it is visible (interpreted by VAM to be its positive or negative existence), its color, its shape (classification), its location (three co-ordinates), and its contents (a list). Each attribute value occupies the specified position on the list defining the object. For example, :B1 is defined as

(((1 1 1), T, :RED, :BLOCK), (1 0 1), ()).

Color and size are permanent attributes; the rest can be changed.

4.1.2 Cases of the Action

The directive case will be defined as the resulting interrelationships between the object of the action and other objects in the environment. In this instance, although the relationships and the object names will be included in the focus, we have arbitrarily decided that such objects were not important enough to have their attributes included in a uniformly-weighted focus. This would tend to simulate the child's orienting response to what is moving or changing, rather than to the background objects.

Objects in the BLOCKs world may hold relationships with other objects, but it is doubtful that reciprocal concepts could be correctly associated with one word until the later strategies, when word order has become significant. For instance, given the concepts left-of and right-of, VAM could not differentiate them at its present level of experience. That is, VAM would have to know the names of both objects before such contrasting concepts could become associated with appropriate words. Therefore, in VAM's world, relations are defined with a single concept representing both a relation and its reciprocal: BESIDE, FRONT-OF (or behind), SUPPORTS (or is-supported-by), BIGGER (or smaller).

When Schank speaks of the recipient case, he gives examples like catching a thrown ball. There is nothing in VAM's experience which could correspond to this case (as two actors are required here), except possibly what we have already described as the directive case. Whichever we call it, the thing to which another object is transferred will be included in the focus. However, we again arbitrarily decided to limit our focus to the resulting state of affairs, excluding the prior situation. It intuitively makes sense that the result of an action would be more noticed than the prior configuration, especially when the comments regarding an event follow the occurrence.

Finally, the instrumental case is another

conceptualization itself, either of the object-state or the
actor-action variety. We will discuss this with examples
when we discuss the particular actions and their inferences.

Thus, we are left with the conceptual representation of
an event as shown in figure 4.2. (The reader may find it
interesting to compare this to Figure 2.4).

4.1.3 Relevant ACTs and Their Inferences

Of Schank's fourteen primitive actions <see section
2.2.1>, only three physical ACTs and one global ACT are
applicable to VAM's world. These are PROPEL, MOVE, GRASP,
and PTRANS. Mental ACTs all require an understanding of the
mental processes within the individual. Schank indicates
that young children are unaware of the Mental ACTs, MBUILD
and CONC, within themselves. Likewise, we doubt that MTRANS
develops very early. Furthermore, the internal functions of
VAM's mental processes is a big problem without Short-Term
Memory, cognitive development, and proceedures for problem-
solving.

Instrumental ACTs would probably not be learnable by a
system with no sensory organs. VAM has representations of
pseudo- aural and visual input, but these (LISTEN-TO and
LOOK-AT), being present in every focus and sentence, would

not develop any clear meaning.

```

```
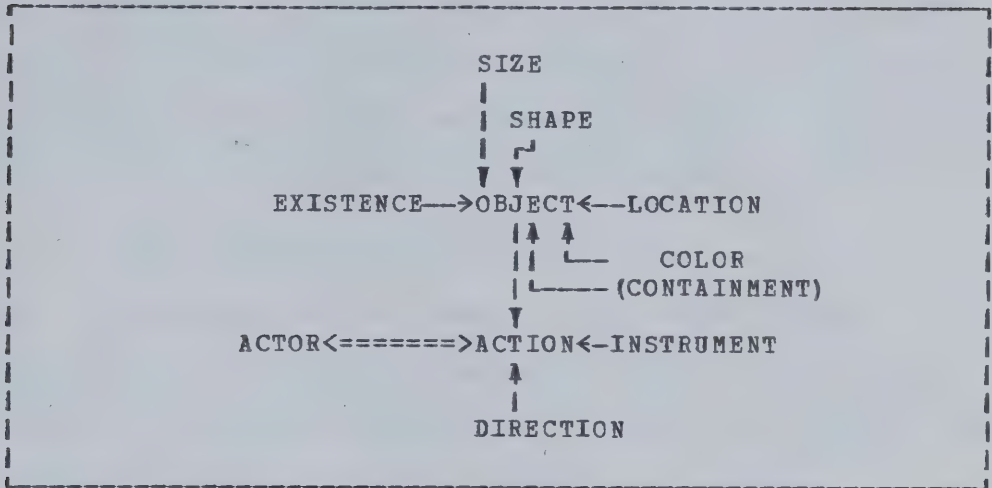

Figure 4.2: Actor-Action Conceptualizations as Seen by VAM

The global ACTs are PTRANS and ATRANS. The latter,
which involves possession, is too abstract to represent in
VAM's world. PTRANS is the change of location for an
object.

Global ACTs are used to represent the way a human
focuses on the result of an ACT, rather than on the ACT
itself. Although Schank insists that PTRANS must result
from a physical ACT upon an object, we use PTRANS to bypass
our problem of having HUMAN action on the environment.
PTRANSing of that object is what VAM perceives.

Schank <1973b> claims that the physical ACTs are all
that one can perform upon an object. None of the fourteen

he lists can portray the concept of turning. Therefore, VAM
will understand a broader PTRANS, consisting of four types,
three of which define rotation through one of an object's
three axes, and one which maintains the original definition:
TURN (Y-axis), TWIST (Z-axis), DROP (X-axis), and RELOC.

Schank <1973b> specifies which inferences can be drawn
when a particular ACT is present. Many refer to the
intentions and feelings of the agent, which do not concern
us here. Of the main inferences of PROPEL, the relevant one
is PTRANS (assuming that the object is not fixed).
Furthermore, the instrument of PROPEL, unGRASP, can also be
inferred. (In contrast to Schank's <1973b> theory, PROPEL
is not used as the instrument of PROPEL in VAM's world, as
domino reactions are not allowed. Also, MOVE is omitted, as
striking an object to propel it would be difficult to
demonstrate in drawings in sufficient detail.)

The only inference of PTRANS is the new location of the
object, and thus its new relationships with new objects.
Its instrument is MOVE or PROPEL, but this is circular when
PTRANS may be inferred from MOVE and PROPEL.

For some reason, Schank states that PTRANS is inferred
by GRASP. We cannot imagine such an instance, and Schank
gives no examples of any. The instrument of GRASP may be
MOVE, but is not necessarily so. Only VAM's arm can move,
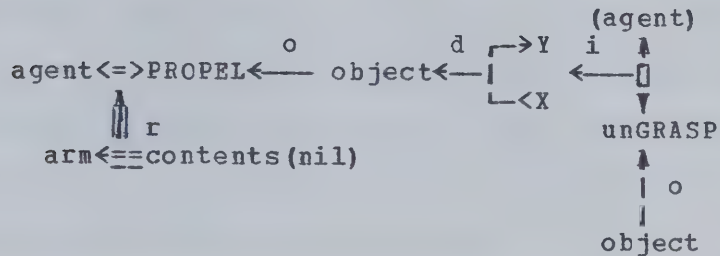

since there are no fingers.

No data was available on the instrument of MOVE.   There
may not be one.   Schank lists no helpful inferences for this
ACT, either, but PTRANS should follow if the body part is
somehow attached to another object, as in the case of
GRASPing something and MOVEing that hand.

To better understand VAM's conceptual capabilities, we
will shortly examine (section 4.3) how the higher level
events interrelate the ACTs and how foci are drawn from
various combinations of these.   In summary, the structure of
the elementary events for VAM and their conceptual
dependency formats, including inferences, are:

PTRANS: to cause an object to change states.

```
                           o            d  ┌─→Y
              agent<=>PTRANS<───object<───│
                         ▲                 └─<X
                         │ r
                   ┌─→Y
object<==(loc) │        OR object<==(facing different direction)
                   └─<X
```

PROPEL: to apply a force to an object, unGRASPing
it in the process.

```
                                          (agent)

                 ▐ r
    arm<═══loc(Y) AND contents of arm<═══loc(Y)
```
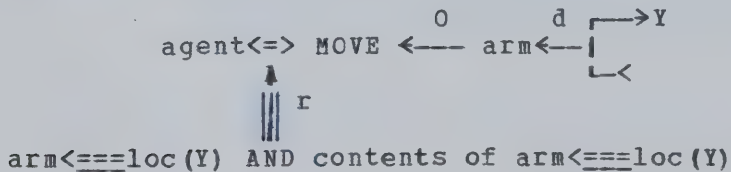

4.2 Objects in the Focus

   Any time the arm is considered to be a part of VAM's
focus of attention, the concept of the arm itself, its color
as defined by the pen parameter used to produce a hard copy,
and its shape are included in the focal list. We assume its
contents to be already part of the focus, as it would be
central to any action involving the arm.

   The object of the action is central to the static
focus. The object itself, its attributes, and its
relationships with other objects are included.

   Any block can enter into the following relationships
with any other block:

   BESIDE   One block is touching sides with
               another.

   FRONT-OF   One block touches another front to back.

   SUPPORTS   The center of gravity of the block on
               top is directly over the lower one.
               There may be other blocks intervening.
               The box may not enter into this
               relationship.

   BIGGER   The shape of two touching objects is the
               same, with each dimension of one greater
               than the corresponding dimension of the
               other.

   Each block may hold one additional relationship to the
box:

   INBOX   The object lies within the box.

The objects and relationships are merged into the focus
in a manner described later.

4.3 Building a Focus

Based on the primitive ACTs, more complicated events
can be built, deriving their foci from the structures of the
individual ACTs involved. For any primitive action, a
single object is specified. The particular program places
its own name, object, and agent in the focus, makes required
state changes on the object's attribute values, then expands
the focus from each object.

> 1. For each object already in the focus, if it is
> related to any other object, then that relation
> and that object are added to the focus.
>
> 2. If the box is in the focus, its contents are
> added to the focus.
>
> 3. Finally, the attribute values of all objects
> in the focus, including the arm, are added to the
> focus.

As in VAS, a focal object set may be indicated to VAM. In
the case of a pointer, only those objects pointed out are
placed in the focus, along with their relationships to each
other and their attributes. We also decided to place the
event's (or program's) name in the focus, as the entire
event should be a learnable concept as well as the component
parts, even though it may have no direct lexical link in the

English language.

Events were shown to VAM, consisting of one or more
primitive ACTs, and their associated cases. In the instance
of PROPEL, the only occurrence was in the act of THROWing,
which included the original definition of PROPEL in addition
to PTRANS, which was implied. Were we to differentiate
THROW from PROPEL, VAM would attach identical weights to the
two concepts for each word involved. Thus, we used PROPEL
as the more complex event. Its focus is:

        VAM PROPEL k
        k PTRANS a(k) r(k) o(k) a(o(k))
        VAM GRASP arm a(arm)

The human can cause an object to be PTRANSed. Although
VAM cannot "see" the human, it would notice the effect on
the environment. The name of this program is WATCH. Given
that the object, k, has attributes a(k), and that it is in
relations r(k) to some other objects o(k), the focus for
this event would be WATCH and the focus of PTRANS:

        WATCH PTRANS (TWIST, DROP, TURN, or RELOC) k a(k)
        r(k) o(k) a(o(k))

Although k serves two functions, as both agent and object,
it is related to its environment only once. This program
would move k to its new position before forming the focus.

VAM can MOVE its arm, possibly PTRANSing its contents,
k. Using squared brackets to indicate conditional

inclusion, the focus for movearm would be:

    MOVEARM VAM MOVE arm a(arm)
    [VAM PTRANS k a(k) r(k), o(k), a(o(k))]

The second part is included if the arm contains the object
k. VAM, of course, would appear only once.

VAM can GOGET an object, k, which requires GRASPing k,
possibly necessitating a preceding unGRASPing of former
contents, k', and/or MOVEing towards k. In accord with our
decision to de-emphasize the pre-action, k' will not be
completely expanded in the focus in its relationships to
other objects. The focus would be:

    GOGET VAM GRASP k a(k) r(k) o(k) a(o(k)) arm
    a(arm)

    [VAM GRASP k' a(k')]
    [VAM MOVE arm]

If VAM lets an object go, PTRANS may be implied unless
the object is already resting on something. The focus for
letgo is:

    LETGO VAM GRASP k a(k) arm a(arm)
    [k PTRANS k a(k) r(k) o(k) a(o(k))]

For the experimental data, PTRANS will always be
included in letgo, because a simple unGRASPing action was
too subtle for appropriate data to be collected.

Finally, VAM may transfer an object, or turn it, by

MOVEing an arm, PTRANSing a GRASPed object. The focus for
this is:

```
TRANSFER VAM PTRANS k a(k) r(k) o(k) a(o(k))
VAM MOVE arm a(arm)
```

The grasping of the object, if necessary, would be part of
the pre-action, and thus is omitted.

4.4 Evaluating the Associations

Each lexical item has associated with it a usage
counter and a list of co-occurring concepts with a count of
the number of times the word and concept have appeared
simultaneously.

A numeric value is used to determine the weight of a
concept-word correspondence. Harris proposed a function
based on time and the weight at time t-1. This involves
keeping records of the previous correlation, which could be
done. However, the use of time is an artificial imposition
upon an environment in which time is not expressed as a
concept. Because of this drawback, and because using
McMaster's formula would provide more controls on the
comparison of VAM to VAS, we choose to correlate concepts
and words as follows. The program keeps a record of

1. The number of times a lexical item has
    occurred,

2. the number of times a concept has appeared in
foci,

and   3. the number of times any concept and any word
have co-occurred.

With this information, VAM is able to decide the most likely

meaning for a given word.

Experimental material for VAM was programmed as a

series of 31 random events, whose resulting environmental

configurations were plotted by computer use of the data

structures. To generate the first of VAM's two experimental

corpora, the resulting series of plots was then shown to a

young child's mother, who provided the corresponding input

data by describing the events to her 1-1/2 year old

daughter. It was hoped that this would provide input

similar to that which a child receives. The following is a

representative sample of corpus 1:

Now the blue box is turned sideways so the thinner
part is facing towards the green box which is in
front of it.

Looks like a book.

And now we've put the small red box on top of the
green box.

Now the little green triangle is on top of the red
box which is in front of the rectangle that looks
like a book.

VAM's second corpus was constructed by VAM's designer, with

the hope of observing the system's optimal performance.

At random points in the experimental runs, we ran a
vocabulary test on VAM to determine a word's meaning to it
(or the closest collection of meanings). If the word was
associated with a concept which is intuitively acceptable,
the word was considered to be learned. If the meaning was
not clear-cut, but if all the meanings associated with the
word together comprised a general definition, the word was
considered correct.

Not only do the number of words learned interest us,
but some particular associations are quite unexpected, and
will be described below.

4.5 Preliminary Experiments and Results

The experiments with VAM were aimed primarily at noting
trends, rather than proving particular hypotheses. We also
wanted to see which of several pairs of alternatives tended
to produce the best results. For instance, VAS's lexicon
was pre-defined by the program, and consisted of those
concepts which McMaster deemed learnable. Words such as the
and if were eliminated as functional words which could have
no meaningful link to an environmental concept. It was
assumed that these would atrophy out of the lexicon when no

clear-cut meaning evolved.

Perhaps, this could eventually happen, but VAM surprised us by attaching definite meanings to function words after several foci:

> MEANING OF A IS :BLOCK
>   and
> MEANING OF IT IS :B5. [1]

However, it became too expensive to pursue this point, and a pre-defined lexicon was used for future interpretations.

Another interesting question was whether the pre-event focus should be part of the focus of the event, in spite of the hesitation to include this. Experimentally, it seemed to have little effect on what VAM learned. One word which was mis-learned when this part of the focus was expanded (get meant :B2), was corrected (to mean #GOGET) when it was excluded. For the rest of the experiments, we chose to follow the original plan of de-emphasizing the pre-action.

Another question arose with precise definition of the variables $u(w)$, $u(c)$, and $u(c,w)$. The usage of a word could mean the total number of times it is used, or the number of sentences in which it occurs. If we consider the former interpretation, words like the would, indeed, tend to

----

[1] The special characters used at the front of VAM's output distinguish concepts from input vocabulary.

decrease in association values, as they would be the most
likely words to re-occur in a single sentence. However,
words with direct environmental referents, would seldom be
affected. We decided to use the former meaning.

The usage of a concept, $u(c)$, could be the number of
times it appears in each focus for all foci, or the number
of foci in which it occurs. The greater $u(c)$, the less the
correlation, all other terms constant, by virtue of the
function itself. Consider the case of an object used in an
event in more than one capacity. We would wish to increase
its connections to the input words. Therefore, we chose to
define $u(c)$ as the number of foci in which a concept
occurred.

Thus, we could define $u(c,w)$ as $u(c)$ x $u(w)$ for a given
focus-sentence pair. In other words, $u(c,w)$ is increased
any time a word is used with a concept, which may be more
than once in a given input.

Another experiment involved segmentation and grouping
of the input data. Harris's use of pre-segmented idiomatic
expressions seemed no less arbitrary than dividing the input
strings at lexical boundaries. A child would be unable to
recognize word boundaries, whereas he could begin to
recognize expressions such as "top-of" as an entity with a
meaning of its own. The results in our experiments were

that hyphenated words received the same meaning and associated weights as each of the two used separately, excluding commonly used words like to. With the limited number of instances in the data in which such expressions occurred, it is difficult to say just how representative our results were.

Furthermore, it was found that the data collected from the mother tended to include more than one comment per focus. We tried two means of inputting this data.

The first method was to run the strings together into one large input string. Intuitively, this is a bad idea, considering the evaluation function. An object which is central to the action could appear more than once in several sentences regarding that action, yet its high occurrence would lower its correlation to the concepts in the focus.

The second procedure was to repeat the focus so that each sentence corresponded to the focus equally. In this way, for n input sentences, VAM learns in the same manner as for n occurrences of the identical event, each with a single associated sentence. We ran experimental versions of VAM which did not expand pre-action foci, using data first which was concatenated into one list per focus, as well as being unedited, and then data which was divided into sentences, reusing the focus, with hyphenated idioms. In the case

where foci were not reused, eleven of the learnable words
were learned. When reusing foci, VAM learned all of the
previously acquired words plus two additional ones.

More verbs were learned in the longer sentences. If
two sentences describing the action only mentioned the
action in the first, separating the input into two
diminished the correlation.

4.6 Correlation Results

We wished to see what differences would become evident
between data drawn from a parent and that of the creator of
VAM, who understood the learning processes. For the basic
approach, we used pre-segmented, hyphenated versions of the
data, with a pre-determined lexicon, reuse of foci, and the
above-established interpretation of the correlation
function.

Finally, we combined the focus-sentence inputs so that
the links were compounded. This provided a larger corpus
and more experience for VAM without the necessity of
obtaining additional data. Corpus three consisted of 42
words, learned from 120 sentence/focus pairs.

Experimental results for corpus one and corpus two are
shown in figures 4.3 and 4.4, respectively. The combined

corpus is in figure 4.5.   Multiple entries under "VAM's meaning" indicate that equal weight was attached to two or more concepts.

Other reasons for words being mislearned are attributed to reasons explained by McMaster <1975> and abbreviated in the "reason for error" column:

> 1.   The scenes in VAS' experience are such that two concepts c1 and c2 always co-occur. In this case, differences in rounding off weights, or chance ordering of the concepts will decide which of c1 and c2 is chosen. This case is called Uniform Concept Co-occurrence (UCC), and parallels a common error in children.
>
> 2.   The corpus contains utterances of the following type: the utterance contains a lexical item whose meaning does not occur in the focus; that is, the utterances contain Misleading Extraneous Words (MEWs).
>
> 3.   The correct meaning of a word w is a concept c whose high usage u(c) lowers the value of F(w,c) to a point where c is not chosen as the meaning of w. This case is called Excessive Concept Usage (ECU).
> <McMaster, 1975, pp.   152-153>

Our interpretation of ECU is that it is caused by a low usage of a word in conjunction with a comparatively high usage of the concepts.   Therefore, words with very low usage which have a direct environmental referent will probably fall into this category.   Adults learning other languages often experience problems with words they have seldom encountered, and children probably do, too.

Results were especially encouraging in that, with

acquired until later.

With corpus 1 VAM did not learn a single binary relationship, but in the other tests, it did learn to associate top-of with #SUPPORTS. #FRONT-OF and #BESIDE were never correctly associated. However, had Winograd's

Figure 4.5: Results Using Combined Corpus

representation been used rather than Schank's, on the same data, results could have been significantly different. VAM had no trouble learning _inside_, _disappeared_ or _gone_, except that #INBOX always co-occurred with :B9 and :BOX, a perfect example of UCC.

In Corpus 1, the word _box_ was used for all objects in the environment except the arm. Correspondingly, VAM associated the word with the concept :BLOCK. In Corpus 2, _box_ and _block_ were used as originally intended. VAM learned the correct correlations in this case. Combining the two, we notice that VAM is somewhat confused.

VAM learns verbs and the permanent attribute of color with less exposure than appears to be required for names of objects. This contradicts what we see in children, but cognitive development may be the major discrepancy between the two. Shapes were not so easily learned.

Finally, in corpus 3, out of 14 verbs and adverbs which could be mapped to verb concepts, 12 were successfully linked to valid concepts.

5

CONCLUSIONS

An attempt has been made here to extend VAS's capabilities to more closely approach that of CLAP in its first strategy. Before continuing to implement strategy I, the VAS/VAM approach should be examined for alternative evaluation procedures. CLAP, itself, should be examined regarding its integrity, noting possible omissions or optional approaches in establishing the desired results.

VAS trivially created a segment list, created a Focal Region and a Focal Structure, and built weighted associations between segments and concepts representing only physical objects, their attributes, and relations between them <McMaster, 1975, pp. 154-155>.

VAM creates a Focal Structure, not from the list of blocks given VAS, but from co-ordinates in three-dimensional space and from the occurrences of actions in the environment. Thus, VAM is capable of building weighted

associations to actions. Due to pre-segmentation, as well
as the absence of time in VAM's environment, there is no
recognition of plural or past-tense forms of the same word
or of their being lexically related.

5.1 Extensions to VAM

Ideally, VAM would be connected to a CRT, or even a
three-dimensional world, which could be visible to the user.
At the present, however, the user must keep track of the
placement of objects so as not to try to place a block in
mid air, and so on. There is enough intelligence in the
programs to make such a block fall, but it must have a level
surface directly under it on which to rest.

Both VAS and VAM are programmed in the MTS version of
Maclisp, which has no interface to other languages or CRT
hardware in the present computer environment. Movement in
the environment can only be performed by the programmer,
with a pre-determined series of events. Even were VAM's
environment a dynamic one, unless the robot were capable of
initiating movement on the environment, the system would be
lacking a very important source of information which a child
has. Perhaps this importance, however, is diminished when
all cognitive processes are pre-specified.

The evaluation of the weight on a word-concept link
deserves some critical consideration. It is uncertain how
any house-keeping will occur during the learning of
segmentation, at the same time maintaining function words in
the lexicon. By re-evaluating each word of an utterance
when it appears in conjunction with a focus, without
considering the meaning the word already has and the word
linked most closely with each concept, CLAP could be guilty
of using less information than that available to the child.
With the static function used, the order in which words were
acquired had no effect on the correlation. Perhaps it
should.

Likewise, one needs to consider the value of salience
to CLAP, and devise some criterion for an orienting
response. Salience could be built in to the function
itself, or the means of constructing the focal list. It
appears that actions should draw CLAP's attention more than
a static scene. There are many more factors to be sorted
out in conjunction with future research in the area of
perception. Finally, the fuction of the parameter m in the
formula, will have to be established before its value can be

accurately determined.[1]

There is another action which comes to mind as an
immediate expansion of VAM, if a sufficiently animated
cartoon could portray it to the person providing verbal
input. HIT is PROPELing an object as a result of MOVEing
the arm, while the arm does not contain it:

```
VAM, PROPEL, k
k, PTRANS, k, a(k), r(k), o(k), a(o(k))
VAM, MOVE, arm.
```

This is a nice event to consider if one has an animated
environment, but it is almost impossible to represent the
verb "hit" in a series of static scenes, in a manner which
prompts relevant input data.

Unlike a child, VAM has a limited external environment.
There is no input corresponding to the stimuli of needs,
wants, pain, emotions, perception (other than visual),
remembering, cognitive development, and complex reasoning.
Some of these things are programmed into the system. For
instance, VAM is programmed to accept each input as data,
and to act upon it, whereas a child may be distracted or
ignore what she sees or hears.

---

[1] An alternative correlation function, which takes into
consideration the focus and sentence totals (and thus the
number of foci/sentences in which the concept/word did not
occur), was tested for a few cases. Results are shown in
Appendix B.

It is difficult to say just how much confidence one can
place in CLAP based on the efforts of VAS and VAM. The
capabilities of CLAP are much greater, even during Strategy
1.

5.2 Towards the Implemetation of Strategy 1

Neither VAM nor VAS did any house-keeping on words
which were not used. This process would be closely linked
to segmentation procedures, whether those outlined by
McMaster are to be implemented, or another is adapted. As
segments are replaced by those with greater meanings, the
nonsense segments must disappear from the vocabulary. To
complete Strategy 1, work will need to be done on the
segmentation, because both VAS and VAM receive pre-segmented
input. This pre-segmentation can be disadvantageous in the
association of morphemes with their concepts. If
segmentation automatically occurs at word boundaries, one
would never learn to recognize "on-top-of" as a single
concept. Likewise, words often contain several morphemes,
such as tense markers, plurality, etc.

Disapproval as an input has not yet been implemented.
Neither is mental maturing a part of VAS or VAM. Similarly,
no attempt has been made to allow an action to stimulate

CLAP to output. Both of these are specified in CLAP's first strategy.

It will be interesting to see just how much of a tool a fully-implemented Strategy 1 will be for future strategies, and to what extent each strategy can and must build upon the preceding one. Hopefully, as CLAP becomes a reality, one will be able to observe many child-like problems and successes.

There is no claim made here as to the completeness of CLAP as a model, in recognition of the fact that the later strategies are skeletal at present. However, in CLAP, we finally have an outline of all the necessary processes, based on current research, of a program which can acquire a language.

APPENDIX.A:
THE CORPORA FOR VAM

Corpus 1

(SEE LOOK AT THAT)
(HMM WHAT'S THAT)
(IS THAT A TRIANGLE INSIDE A BOX, EH)

(YES NOW WE HAVE THIS TRIANGLE THAT'S DISAPPEARED FROM THE
TOP OF THIS BOX, THE SQUARE BOX)
(AND THE TALL BLUE BOX IS BEHIND IT)
(THERE'S THIS BLACK BOX TO THE RIGHT OF THAT)

(LOOK, THERE'S NOW THIS BOX ON TOP OF THAT BOX, SEE)
(AND ALL THE OTHER BOXES ARE IN THE SAME PLACE EXCEPT FOR
THIS LITTLE ONE BEHIND HERE)
(HMM, SEE THAT RED ONE)
(NO ANITA DOESN'T SEE IT)

(NOW THE BLUE BOX IS GONE FROM INSIDE OF THE BOX TO THE TOP
OF THE RED BOX)
(LOOKS LIKE A THREE-SIDED FIGURE)

(AND THIS BOX IS HOLLOW WITH A LITTLE BOX INSIDE THE BLACK
BOX)

(WELL THIS BOX HAS BEEN TURNED OVER ON ITS SIDE THAT'S
WHAT'S HAPPENED)
(I THINK ALL THE OTHER ONES ARE IN THE SAME PLACE)

(AND THESE ARE ALL DIFFERENT SIZES)
(ONE BOX IS GONE FROM THE PICTURE)
(THAT'S THE AH TALLEST RECTANGULAR FIGURE THE ONE THAT'S
GONE)
(WELL IT'S POINTED, WHAT IS IT)
(TRIANGLE, SORRY I HAD IT WRONG)

(OH THERE, LOOK, THERE'S SOME LITTLE BOXES THERE)
(YEAH AND THERE'S A GREEN ONE ON TOP OF A RED ONE)
(AND ON TOP OF THAT ONE IS A BLUE TRIANGULAR BOX)
(GREEN BOX AND A BLUE THIN BOX BEHIND THAT)
(AND A BLACK BOX WITH A GREEN BOX INSIDE)

(NOW LOOK, ANITA, THAT'S HANGING IN THE AIR, THIS ONE)
(IT'S NOT SITTING ON ANYTHING)

(IT'S BEING MOVED)
(YEAH, THAT LITTLE TINY GREEN ONE)
(THAT LITTLE TINY GREEN ONE, YEA)
(DID YOU KNOW THAT THIS WAS A SQUARE BOX ANITA)
(THIS ONE HERE, THIS GREEN ONE)
(I THINK YOU'D CALL THAT A CUBE)
(ANITA DID YOU KNOW THAT THEY USED TO BUILD PYRAMIDS LIKE IN
TRIANGLES)

(NOW THAT LITTLE GREEN GUY HAS BEEN DROPPED FROM THE MIDDLE
OF THE AIR AND SITTING DOWN)
(IF ANYTHING ELSE HAPPENED I DON'T KNOW)

(THE RED ONE THE RED TRIANGLE YOUR BOX THAT HAS DISAPPEARED
HAS NOW REAPPEARED IN THE BLACK BOX)
(AND ALL THE OTHER BOXES ARE IN THE SAME PLACE)

(NOW THE BLUE BOX IS TURNED SIDEWAYS SO THE THINNER PART IS
FACING TOWARDS THE GREEN BOX WHICH IS IN FRONT OF IT)
(LOOKS LIKE A BOOK)
(AND NOW WE'VE PUT THE SMALL RED BOX ON TOP OF THE GREEN
BOX)
(NOW THE LITTLE GREEN TRIANGLE IS ON TOP OF THE RED BOX
WHICH IS ON TOP OF THE GREEN BOX WHICH IS IN FRONT OF THE
RECTANGLE THAT LOOKS LIKE A BOOK)
(AND ALL THE OTHER FIGURES LOOK THE SAME)

(NOW WE'VE GOT THE TRIANGLE IN MIDAIR)
(THE COMPUTER KNOWS IT'S HOLDING IT UP THERE IN MIDAIR EH)
(NOW THERE'S NOTHING MORE INTERESTING ABOUT THAT)
(WE'LL SEE WHERE THAT THING GOES)
(IT'S GONE)
(LOOK WHAT HAPPENED IT FELL DOWN)
(SEE, IT FELL DOWN)
(HEY THAT'S A RED BOX)
(OH NO LOOK AT THAT)
(AND ALL THE OTHER BOXES ARE THE SAME)
(THE RED BOX IS SHORT NOW BECAUSE IT'S NOT STANDING UP ON
END ANYMORE)

(AND NOW WE PUT THE GREEN BOX ON TOP OF THE RED BOX AND MOVE
THE OOP THE GREEN OTHER GREEN BOX FROM THE OUTSIDE AND PUT
THAT IN IT IN FRONT OF THE BLUE BOOK)
(AND THE TRIANGLE'S STILL IN THE BLACK BOX)

(NOW WE'VE PICKED UP THE BOOK THE, COMPUTER'S PICKED UP THE
BOOK THAT IS)

(AND MOVED IT IN FRONT OF THE BLACK BOX)
(LOOK NOW WE'VE JUST LET'S SEE)
(ANITA ANITA WHAT'S THAT)
(THAT'S A BOX)

(THAT'S A BOX)

(NOW THE BOOK IS ON ITS BACK)
(SEE THE BLUE BOOK FALL)

(NOW THE COMPUTER'S GONNA PICK UP THE BOOK)
(YEAH IT'S GONNA PICK UP THE BOOK)

(IT DIDN'T PICK UP THE BOOK)
(IT DID SOMETHING ELSE)
(NOW WE'VE GOT THE TRIANGLE ON TOP OF THE BOX, THEREFORE)
(THEY'RE BOTH BLUE)
(IT'S GOT A RED TRIANGLE IN THE BLACK BOX)

(NOW THE RED THIN TALL TRIANGLE IS GONNA BE PICKED UP)
(NO THERE'S NOTHING NEW IN THERE)

(NOW WE'RE PUTTING IT SOMEWHERE)

(WE PUT THE RED TALL TRIANGLE BEHIND THE BLUE FAT TRIANGLE)
(IT'S THE FATTEST ONE)

(NOW THE SMALLEST TINY TRIANGLE THE GREEN ONE IS BESIDE THE
BLUE FAT TRIANGLE WHICH IS IN FRONT OF THE SKINNY TRIANGLE)

(OK NOW THE SMALL RED BLOCK IS GONE FROM ON TOP OF THE GREEN
BOX)
(THAT'S THE TINIEST BLOCK)

(NOW HE'S TAKING THE GREEN BOX B3 AND PUTTING IT INSIDE THE
BLACK BOX)
(IT'S ABOUT THE SAME SIZE AS B7 WHICH IS SITTING ON TOP OF
THE RED LONG RECTANGULAR BOX)

(NOW WE'RE TAKING THE FAT BLUE TRIANGLE AND PUTTING IT ON
TOP OF THE GREEN BOX WHICH IS ON TOP-OF THE RED LONG
RECTANGULAR BOX)

(NOW WHAT HAPPENED)
(THIS ONE WAS GONE AND NOW IT'S ON TOP I THINK)
(YEA I'M RIGHT)
(THE LITTLE TINY RED BLOCK ON TOP-OF THE GREEN BOX INSIDE
THE BLACK BOX BEHIND THE THIN BOX)

(NOW WE'RE TAKING THE TALL TRIANGLE AND PUT IT ON TOP-OF THE
SMALL BLOCK INSIDE THE BLACK BOX AND LEFT EVERYTHING ELSE
THE SAME)

Corpus 2

(THE COMPUTER'S ARM IS ABOVE B5 , THE RED PYRAMID)
(WE HAVE NINE BLOCKS THREE ARE GREEN TWO ARE BLUE AND THREE
ARE RED AND A BLACK BOX)

(VAM MOVED B5 BEHIND B3)

(VAM MOVED B7 TO THE TOP OF THE OTHER GREEN BLOCK , B3)

(VAM MOVED B4 TO THE TOP OF B6)

(B7 IS INSIDE THE BLACK BOX)

(VAM TURNED B7 OVER)

(B5 , THE RED PYRAMID , DISAPPEARED)

(VAM WENT TO GET B2)

(VAM LIFTED B2 , THE LITTLE GREEN PYRAMID , AND MOVED IT)

(VAM DROPPED B2)

(B5 IS BACK AGAIN , INSIDE THE BLACK BOX)

(B8 GOT TURNED AROUND BY VAM)

(THE RED CUBE IS ON TOP OF THE GREEN CUBE , B3)

(VAM PUT B2 ON TOP OF B1)

(VAM PICKED UP B4)

(VAM THREW B4 AWAY)

(VAM KNOCKED B6 OVER)

(B7 IS MOVED ON TOP OF B6)

(VAM PICKED UP B8 , THE BLUE BLOCK)

(B8 GOT DROPPED)

(B8 TURNED OVER ON ITS SIDE)

(VAM PUSHED THE BLUE BLOCK OVER SOME MORE)

(B4 , THE BLUE PYRAMID , GOT PUT ON TOP OF THE BLUE BLOCK ,
B8)

(VAM WENT TO GET B5 WHICH IS STILL INSIDE B9)

(VAM PICKED UP B5 AND MOVED IT OUT OF THE BOX)

(VAM DROPPED B5 BEHIND THE BLUE PYRAMID)

(VAM PICKED UP B2 AND SET B2 DOWN BESIDE THE BLUE PYRAMID ON
TOP OF THE BLUE BLOCK B8)

(B1 DISAPPEARED)

(VAM MOVED B3 , ONE OF THE GREEN CUBES , INSIDE THE BLACK
BOX)

(VAM STACKED B4 ON TOP OF B7 WHICH IS ON TOP OF B6)

(B1 IS BACK ON TOP OF B3 WHICH IS STILL INSIDE B9)

(NOW THE RED PYRAMID IS ON TOP OF THE TINY RED BLOCK WHICH
IS SITTING ON TOP OF THE GREEN CUBE IN THE BOX)

APPENDIX B: PRELIMINARY RESULTS WITH AN ALTERNATIVE

CORRELATION FUNCTION

An alternative correlation function was tested on five words from the combined lexicon. Preliminary results indicate that this method may be superior to the function, F, used for both VAS and VAM, and described in section 3.2.4.

The formula assumes $u(c)$, $u(w)$, and $u(c,w)$, are Bernouilli random variables, where:

$u(c) = $ 1 if the concept, c, appears in a given focus
            0 otherwise

$u(w) = $ 1 if the word, w, appears in a given sentence
            0 otherwise

$u(c,w) = $ 1 if both c and w occurred in an input pair
             0 otherwise

With n being the number of input sentence/focus pairs, the correlation was computed as being:

$$[n \ u(c,w) - u(c) \ u(w)] \ / \ u(c) \ u(w) [n - u(c)] [n - u(w)]$$

VAM learned three of the five words with VAS's formula. With the new correlation, it would have learned four.

The results are shown in the following figures, which list those concepts ranked among the top five by at least one of the functions. From these results, one can see that there are some differences in the ordering of the top-ranked associations of the two formulae.

CONCEPT	OLD CORRELATION	OLD RANK	NEW CORRELATION	NEW RANK
#SUPPORTS	6.96000	1	.17056	1
:B3	6.64000	2	.15909	3
:B1	6.06800	3	.15959	2
:CUBE	6.58200	4	.15196	5
#TRANSFER	6.53500	5	.15193	6

#TRANSFER	19.84199	6	.32551	4

Figure B.4: Comparisons of the Word _VAM_

CONCEPT	OLD CORRELATION	OLD RANK	NEW CORRELATION	NEW RANK
:PYR	20.74400	1	.31001	1
RELOC	17.26400	2	.16482	4
#SUPPORTS	15.79999	3	.15167	6
PTRANS	15.21649	4	.08150	13
:RED	15.18549	5	.19352	3
:B5	13.22799	9	.20567	2
#BIGGER	8.7400	15	.16087	5

Figure B.5: Comparisons of the Word _Triangle_

One advantage of the second correlation function is
that one can find its confidence intervals. Using the
confidence coefficient of 95%, the results of the probable
meaning for each word was as follows:

TRIANGLE-:PYR   +.16 ≤ .31001 ≤ +.46

    VAM-#VAM   +.26 ≤ .39642 ≤ +.54

MOVED-#MOVEARM   +.16 ≤ .30441 ≤ +.46

    B8-:B8   +.15 ≤ .28098 ≤ +.45

BLOCK-#SUPPORTS   -.03 ≤ .17056 ≤ +.30

(These ranges are approximations only, derived from a table
which assumes bivariate normal distributed random variables
<Pearson and Hartley, 1956, p. 140>). This indicates that
VAM could not place great confidence in these meanings,
especially the meaning for _block_. More work must be done in

this area before any concrete conclusions can be drawn.
